The Journal of Personality and Social Psychology publishes original reports of research, methodology, theory, criticism, and literature review in the fields of personality and social psychology of normal processes and populations. Submitted manuscripts should delineate an important question and provide a clear answer to it. In the case of research reports, this will often require demonstration that the reported results are generalizable beyond a single research setting. Consult the editorial in the January 1979 issue (Vol. 88, pp. 1–7) for a detailed statement of policies and instructions to authors.

Manuscripts: Submit manuscripts in quadruplicate, prepared according to the *Publication Manual of the American Psychological Association* (2nd ed.). Copies should be highly legible and will not be returned to authors unless they are original typewritten copies. Mail manuscripts to the Acting Editor, Clyde Hendrick, Department of Psychology, Box 8433, University of Miami, Coral Gables, FL 33124.

Required supplementary information: Manuscripts cannot be accepted for publication unless the author provides supplementary information in the following categories: (a) a cover letter that indicates the relation (or the lack of relation) of the submitted manuscript to other papers by the same author (a) that are currently submitted, in press, or recently published; (b) one copy of each such cited paper; (c) one copy of a statement of the procedures of the research reported in the submitted manuscript in sufficient detail to serve as a guide for conduct of an exact replication; and (d) one copy of the summary tables (e.g., correlation tables, analysis of variance summaries) for the major analyses reported. If it appears that the supplementary materials in categories (c) or (d) might be bulky, the author should exercise judgment and restraint in selecting what to send. It is not necessary to send supplementary material that repeats verbatim manuscript content.

After a manuscript is accepted, authors will be expected to provide assurance that their data are available in unanalyzed form for reanalyses by other investigators and that their research procedures were consistent with the American Psychological Association's published principles of research ethics, except insofar as may be detailed otherwise in the manuscript.

Copyright and Permission: All rights reserved. Written permission must be obtained from the American Psychological Association for copying or reprinting text of more than 500 words, tables, or figures. Permission is normally granted contingent upon like permission of the author, inclusion of the APA copyright notice on the first page of reproduced material, and payment of a fee of $10 per page, table, or figure. Abstracting is permitted with credit to the source. Permissions and fees are waived for authors who wish to reproduce their own material for personal use; fees only are waived for authors who wish to use their own material commercially. Permission and fees are waived for the photocopying of isolated articles for nonprofit classroom or library reserve use by instructors and educational institutions. Libraries are permitted to photocopy beyond the limits of U.S. copyright law: (1) those post-1977 articles with a code at the bottom of the first page, provided the per-copy fee indicated in the code is paid through the Copyright Clearance Center, P.O. Box 765, Schenectady, NY 12301; (2) pre-1978 articles, provided that the per-copy fee stated in the Publishers' Fee List is paid through the Copyright Clearance Center, P.O. Box 765, Schenectady, NY 12301. Address requests for reprint permission to the Permissions Office, APA, 1200 Seventeenth Street, N.W., Washington, D.C. 20036.

Subscriptions: Subscriptions are available on a calendar year basis only (January through December). Nonmember rates for 1979: $60 domestic, $64 foreign, $6 single issue. APA member rate: $20. Write to Subscription Section, APA.

Change of Address: Send change of address notice and a recent mailing label to the attention of the Subscription Section, APA, 30 days prior to the actual change of address. APA will not replace undelivered copies resulting from address changes; journals will be forwarded only if subscribers notify the local post office in writing that they will guarantee second-class forwarding postage.

Reprints: Authors may order reprints of their articles from the printer when they receive proofs.

Back Issues and Back Volumes: For information regarding back issues or back volumes write to Order Department, APA.

Microform Editions: For information regarding microform editions write to any of the following: Johnson Associates, Inc., P.O. Box 1017, Greenwich, Connecticut 06830; University Microfilms, Ann Arbor, Michigan 48106; or Princeton Microfilms, Princeton, New Jersey 08540.

Published monthly in one volume per year by the American Psychological Association, Inc., 1200 Seventeenth Street, N.W., Washington, D.C. 20036. Printed in the U.S.A. Second-class postage paid at Washington, D.C., and at additional mailing offices.

Stressful Life Events, Personality, and Health: An Inquiry Into Hardiness

Suzanne C. Kobasa
University of Chicago

Personality was studied as a conditioner of the effects of stressful life events on illness onset. Two groups of middle and upper level executives had comparably high degrees of stressful life events in the previous 3 years, as measured by the Holmes and Rahe Schedule of Recent Life Events. One group ($n = 86$) suffered high stress without falling ill, whereas the other ($n = 75$) reported becoming sick after their encounter with stressful life events. Illness was measured by the Wyler, Masuda, and Holmes Seriousness of Illness Survey. Discriminant function analysis, run on half of the subjects in each group and cross-validated on the remaining cases, supported the prediction that high stress/low illness executives show, by comparison with high stress/high illness executives, more hardiness, that is, have a stronger commitment to self, an attitude of vigorousness toward the environment, a sense of meaningfulness, and an internal locus of control.

An exceptional number of studies in the last 20 years (cf. Dohrenwend & Dohrenwend, 1974; Gunderson & Rahe, 1974) have suggested that stressful life events precipitate somatic and psychological disease. This article considers the importance of personality as a conditioner of the illness-provoking effects of stress.

During the last decade, investigators have shown that the recent life histories of hospitalized persons contain significantly more frequent and serious stressful events than do histories of matched controls from the general population (e.g., Paykel, 1974) and that Navy personnel who begin a cruise with high stress scores suffer more illness episodes during the months at sea than do sailors who start out with low stress scores (Rahe, 1974). But the possibility of a causal connection between stress and illness is hardly a new idea. Physicians, philosophers, and persons simply

This article is based on the author's doctoral dissertation (Kobasa, 1977), submitted to the Department of Behavioral Sciences at the University of Chicago. The preparation of this manuscript was supported in part by Public Health Service Grant MH-28839-01 from the National Institute of Mental Health. The author wishes to thank Robert R. J. Hilker, James Kennedy, and all of the executives who participated in the study. Special appreciation is extended to Salvatore R. Maddi who supervised the project. Chase P. Kimball, David E. Orlinsky, and Marvin Zonis contributed many useful suggestions as dissertation committee members.

concerned about staying healthy have long wondered about the etiological significance of life events. The distinctiveness of recent research lies in its attempt to define and measure stress.

In the current studies, a life event is defined as stressful if it causes changes in, and demands readjustment of, an *average person's normal routine*. This definition of stress has relied upon the empirical demonstration (Holmes & Masuda, 1974; Holmes & Rahe, 1967) that there is a general consensus about the degree to which specific life occurrences involve change and require readjustment. This consensus emerged from the ratings of stressfulness of a long list of events made by thousands of subjects varying in age, sex, socioeconomic status, race, cultural background, education, and religion. From this consensus, stressfulness weights for the life events were obtained.

Deriving from this research is the Schedule of Recent Life Events (Holmes & Rahe, 1967), which contains positive (e.g., marriage), negative (e.g., illness of a family member), frequent (e.g., minor traffic violation), and rare (e.g., death of a child) occurrences. The associated Social Readjustment Rating Scale (Rahe, Lundberg, Theorell, & Bennett, 1971) gives the consensual weights for these events (e.g., on a scale from 1 to 100, divorce gets a mean score of 73 and vacation, a score of 13). The stressfulness of a particular person's life is measured in this procedure by finding out what events he or she has encountered and scoring the occurrences according to their consensually quantified weights.

This consensual approach to stress as measurable environmental input has allowed easy collection of large amounts of data and uncomplicated analysis of the statistical relationship between stressful life events and illness onset. The findings of stress research have had dramatic impact in both professional journals and popular magazines. In the journals (e.g., Rabkin & Struening, 1976), one usually finds some caution urged about too quickly concluding a causal relationship between stress and illness on the basis of correlational and methodologically weak studies. This warning is mitigated, however, by a sense of optimism that there is something to this stress and illness connection and a wish for studies that are more sophisticated in design and methods of analysis. But in the popular literature (e.g., Wolfe, 1972), final conclusions have already been drawn. Readers are provided with a self-administered stress test and told the likelihood of illness associated with each total stress score (e.g., a score above 300 means an 80% chance of getting sick). Readers whose stress scores are high are warned that if they wish to remain healthy they should avoid additional stressful encounters, even to the point of shunning such everyday necessities as driving on the Los Angeles Freeway.

This advice seems inadequate, insofar as modern life can be characterized as inherently stressful (Brodsky, 1977; Toffler, 1970). A person might indeed be able to keep from getting married or taking on a new mortgage, but how can one prevent the effects of pollution and overcrowding or of being assigned to a different job when his or her company signs a new contract? Further, increasing levels of stress tend to coincide with increasing opportunities and potential resources (Kobasa, Hilker, & Maddi, Note 1). By avoiding stress, modern persons may be turning away from a chance to better their lives.

Before deciding to avoid stressful life at any cost, one should consider the actual magnitude of the relationship between stress and illness. Although correlations range from .20 to .78, the majority fall below .30, and in Rahe's naval data, the correlations are consistently around .12 (Rabkin & Struening, 1976). Many stress and illness researchers, in their preoccupation with group means, have failed to question the distribution of their data. Variability of both stress and illness scores within groups has been observed to be extreme in several studies (Wershow & Reinhart, 1974). One likely explanation for these data is the presence of subjects with high stress scores who are not getting sick. Oddly, such subjects have been overlooked in the popular and professional literature on stress and illness.

Studying Stressed but Healthy Persons

In contrast, the present study considers how highly stressed subjects who remain healthy differ from those who show illness along with high stress. Studying the individual who undergoes high degrees of stress without falling ill amounts to inquiring about the mediating factors that affect the way one reacts to stress. Holmes and Masuda (1974) and the majority of other stress investigators attempt to draw a direct causal link between the occurrence of stressful life events and the onset of illness by reference to the physiological model of a stress reaction formulated by Hans Selye (1956). Stressful life events are said to evoke "adaptive efforts by the human organism that are faulty in kind or duration, lower 'bodily resistance' and enhance the probability of disease occurrence" (Holmes & Masuda, 1974, p. 68). Holmes and others, however, fail to take into account what Selye goes on to say about individual differences and the stress reaction. In the study described in this article, the more subtle points in Selye's work are referred to, in the attempt to consider factors in the stress reaction that serve to deflect the negative impact of stressful events. Mediators of the stress and illness connection, which probably include physiological predisposition, early childhood experiences, and social resources, as well as the mediator emphasized here, personality, are together responsible for what Selye calls the distinctive way in which each individual "takes to" stressful life occurrences.

The proposition of this study is that persons who experience high degrees of stress without falling ill have a personality structure differentiating them from persons who become sick under stress. This personality difference is best characterized by the term *hardiness*. The conceptual source of the supposition, in contrast to the passive and reactive view of humankind found in most stress and illness work, is a set of approaches to human behavior that Maddi (1976), in his categorization of the major personality theories, calls fulfillment theories. The hardy personality type formulated here builds upon the theorizing of existential psychologists (Kobasa & Maddi, 1977; Maddi, 1975) on the strenuousness of authentic living, White (1959) on competence, Allport (1955) on propriate striving, and Fromm (1947) on the productive orientation. Hardy persons are considered to possess three general characteristics: (a) the belief that they can control or influence the events of their experience, (b) an ability to feel deeply involved in or committed to the activities of their lives, and (c) the anticipation of change as an exciting challenge to further development. Much research has already shown the advantages in behavior of control (e.g., Lefcourt, 1973; Rodin & Langer, 1977; Rotter, Seeman, & Liverant, 1962; Seligman, 1975), commitment (e.g., Antonovsky, 1974; Kobasa & Maddi, 1977; Lazarus, 1966; Lazarus, Averill, & Opton, 1974; Moss, 1973), and challenge (Fiske & Maddi, 1961; Maddi, 1967). In discussing the hypotheses presented below, the implications of theory and research concerning these three general characteristics are extended to considerations of health and illness.

Hypothesis 1. Among persons under stress, those who have a greater sense of control over what occurs in their lives will remain healthier than those who feel powerless in the face of external forces. Following the model proposed by Averill (1973) to explain his laboratory observation that some organisms are not debilitated by stressful stimuli, the highly stressed but healthy person is hypothesized to have (a) decisional control, or the capability of autonomously choosing among various courses of action to handle the stress; (b) cognitive control, or the ability to interpret, appraise, and incorporate various sorts of stressful events into an ongoing life plan and, thereby, deactivate their jarring effects; and (c) coping skill, or a greater repertory of suitable responses to stress developed through a characteristic motivation to achieve across all situations. In contrast, the highly stressed persons who become ill are powerless, nihilistic, and low in motivation for achievement. When stress occurs, they are without recourse for its resolution, give up what little control they do possess, and succumb to the incapacity of illness.

Hypothesis 2. Among persons under stress, those who feel committed to the various areas

of their lives will remain healthier than those who are alienated. Committed persons have a belief system that minimizes the perceived threat of any given stressful life event. The encounter with a stressful environment is mitigated by a sense of purpose that prevents giving up on one's social context and oneself in times of great pressure. Committed persons feel an involvement with others that serves as a generalized resistance resource against the impact of stress (Antonovsky, 1974). Committed persons have both a reason to and an ability to turn to others for assistance in times demanding readjustment.

Although commitment to all areas of life—work, social institutions, interpersonal relationships, family, and self—should be characteristic of highly stressed persons who do not fall ill, one area is singled out as particularly important for health. Staying healthy under stress is critically dependent upon a strong sense of commitment to self. An ability to recognize one's distinctive values, goals, and priorities and an appreciation of one's capacity to have purpose and to make decisions support the internal balance and structure that White and other theorists (cf. Coelho, Hamburg, & Adams, 1974) deem essential for the accurate assessment of the threat posed by a particular life situation and for the competent handling of it.

Hypothesis 3. Among persons under stress, those who view change as a challenge will remain healthier than those who view it as a threat. Persons who feel positively about change are catalysts in their environment and are well practiced at responding to the unexpected. Because they value a life filled with interesting experiences, change seekers have well explored their environment and know where to turn for resources to aid them in coping with stress. They have a predisposition to be cognitively flexible, which allows them to integrate and effectively appraise the threat of new situations. Their basic motivation for endurance allows them to persist even when the new information is exceedingly incongruous and, thereby, maximally provoking of strain and illness (Moss, 1973).

Given the characterization of hardiness contained in the first two hypotheses, it should be clear that the highly stressed but healthy individual is not engaging in irresponsible adventurousness. At the core of the search for novelty and challenge are fundamental life goals that have become, in adulthood, increasingly integrated in a widening diversity of situations (Henry, 1968; Neugarten, 1974).

Although personality is the primary concern of the study reported here, other kinds of variables may well differentiate the highly stressed and healthy from those who have fallen ill under stress. These would include a variety of psychological, social, physiological, and environmental mediators. In order to increase understanding of those who fall ill and stay healthy under high stress, the present study included information concerning various demographic characteristics and perceptions of stressfulness of events.

Method

Overview

The first task was the identification of high stress/low illness and high stress/high illness groups. For this purpose, all members ($N = 837$) of a large subject pool were mailed a stress and illness questionnaire. They were asked to report, by month and year, which of a list of stressful life events and illness episodes they had experienced in the previous 3 years. A total stress score and a total illness score were obtained for each subject by the standard procedure of noting the items checked and multiplying these by their frequencies and consensually defined weights. Subjects were then assigned to one of the two groups or put aside. Assigned to the high stress/low illness and high stress/high illness groups were 126 subjects above the median for total stress and below the median for total illness and 200 subjects above the median for total stress and above the median for total illness, respectively. Discarded subjects included 322 low-stress cases and 22, or all of the female subjects. In further group refinement, 40 high stress/high illness cases whose peak illness score preceded rather than followed their peak stress score and 10 borderline cases from each of the two groups were put aside. Finally, because of a request from the company for which all of the subjects worked that the sample to be administered personality questionnaires be kept at a workable minimum, a set of 100 subjects was randomly selected from the 116 remaining high stress/low illness cases and 100 randomly selected from the 150 remaining high stress/high illness subjects.

Within 3 months of the stress and illness testing, the two groups were mailed another questionnaire. This questionnaire contained several personality tests

along with questions about demographics and perception of life stressfulness.

The data from approximately half of each group were used to test hypotheses concerning group differences in hardiness. Data from the remaining cases in each group were used to cross-validate the results. The division of the groups into test and cross-validation cases was necessitated by the statistical technique relied upon in the study, discriminant function analysis, which has been characterized in previous research by problems of generalizability due to instability of results (cf. Huberty, 1975). Although powerful as a tool for looking at group differences, discriminant function analysis, like regression analysis, has not always provided results that hold up in the making of inferences from sample results to some population, and over repeated samplings. Until a replication of the study is possible, the use of a "holdout sample" must be relied upon for an accurate test of the adequacy of the derived discriminant function that defines group differences.

Subjects

This study required a subject pool both large and stressed enough to obtain sufficiently large groups for study. All of the middle and upper level executives of a large public utility served as the pool from which groups were selected. This utility, in the year prior to the onset of the study, had entertained serious discussion (in executive seminars, company publications, and consultations with the medical department) of the increasing numbers of stressful events faced by executives. These events consisted of changes instituted by the utility itself, like a program of job evaluations that led to some promotions and many more demotions, as well as requirements for readjustment from external sources, such as the federal government's affirmative action demands. These changes, coupled with the expected usual range of personal and family stresses, suggested that stress scores for the subject pool would be generally high.

Demographically, the pool was quite homogeneous. The modal characteristics of the subjects were (a) male gender; (b) 40 to 49 years of age; (c) married, with two children; (d) on the third or middle management level, and having been there for 6 years or more; (e) possessing at least a college degree; (f) wife not working outside the home; (g) usually Protestant, and attending religious services very or fairly often.

Measurement of Stress and Illness

The most frequently used scales in stress and illness research, the Schedule of Recent Life Events and the Social Readjustment Rating Scale (Holmes & Rahe, 1967), were employed in this study. Additions to these scales were made on the basis of pilot testing. The majority of additions were more detailed specifications of the original items, modeled after suggestions from other adapters of the test (Hough, Fairbank, & Garcia, 1976; Paykel, 1974). Each of the most ambiguous events was replaced by two events, one presenting the positive form of the Holmes and Rahe item and the other, the negative version. "Change in financial state," for example, was translated into "improvements in financial state" and "worsening of financial state." These specifications were given the seriousness weights of the items from which they were derived. Other additions to the Holmes and Rahe list were based on a pilot use of the test with 50 randomly selected executives. In response to the question "What other events have you experienced during the past 3 years?", these subjects reported 15 events not found on the original list. Most of these referred to occurrences at work. Seriousness weights were assigned to these additions by the investigator and 20 other judges using the ratio scale judgment procedure of Holmes and Rahe (1967).

The illness items in the stress and illness questionnaire were taken from the Wyler, Masuda, and Holmes (1968) Seriousness of Illness Survey. After consultation with the medical director of the executives' company, 118 of the diseases listed in this survey were chosen as applicable to the pool being tested. Each illness item is characterized by a seriousness weight based on a consensual agreement of numerous and diverse judges (both medical and lay) and is obtained in a manner similar to the derivation of the Social Readjustment Rating Scale. The reliability and validity of this scale as a complete listing of disease syndromes in a form accessible to both laypersons and physicians, and as an accurate set of evaluations of the general seriousness of various distinct illnesses, has been established (cf. Wyler, Masuda, & Holmes, 1970).

Measurement of Personality, Demographic, and Perception Variables

A composite questionnaire, made up of all or parts of four standardized and two newly constructed instruments, was designed to test the three personality hypotheses. The standardized tests were chosen for their theoretical relevance and empirical reliability and validity. All of the instruments are appropriate for use with a sample of executives (i.e., a group of well-educated adult professionals who are relatively free of gross psychopathology).

The *control* dimension was measured through four different instruments. What has been called decisional control or autonomy was measured through the Internal–External Locus of Control Scale (Lefcourt, 1973; Rotter, Seeman, & Liverant, 1962), and the Powerlessness versus Personal Control scale of the Alienation Test (Maddi, Kobasa, & Hoover, Note 2). The latter instrument also provided a way of measuring cognitive control (i.e., the ability to find meaning in stressful life events) in its Nihilism versus Meaningfulness scale. Coping skill (i.e., the availability of responses with which to deal with stressful life events) was measured through the Achievement scale of the Personality Research Form (Jackson, 1974; Wiggins, 1973).

The question of whether these forms of control are accompanied by a need to dominate the behavior of others was addressed through administration of the Leadership Orientation scale of the California Life Goals Evaluation Schedules (Hahn, 1966) and the Dominance scale of the Personality Research Form (Jackson, 1974).

The *commitment* dimension was measured by the Alienation Test (Maddi et al., Note 2). Of relevance here are the alienation versus commitment scores this test yields in five areas of functioning (work, social institutions, interpersonal relationships, family, and self). The degree of consistency across a subject's different forms of involvement was also tested. This was done through the Role Consistency Test, adapted from the Gergen and Morse (1967) Self-Consistency Test to measure the compatibility among the subject's reported five most important life roles.

Measurement of the orientation to *challenge* required the administration of several tests. The degree to which the executive sought out rather than avoided stimulation from his environment was measured through the Preference for Interesting Experiences scale of the Hahn (1966) test and the Vegetativeness versus Vigorousness scale of the Alienation Test. The executive's ability to seek challenge even in the face of potential psychological, social, and biological threat was indexed by Hahn's scale of Security Orientation. Cognitive flexibility versus cognitive rigidity was measured through the Need for Cognitive Structure scale of the Personality Research Form and the ability to persist even in the most challenging environment, through the Need for Endurance scale of the same instrument. Finally, the degree to which an orientation toward challenge was characterized by a general sense of responsibility toward life's demands was measured through the Adventurousness versus Responsibility scale of the Alienation Test.

Subjects were asked about three demographic characteristics: age, job level (third, fourth, fifth, and officer), and number of years spent at current level. Executives were also asked to rate on a scale of 1 (not at all stressful) to 7 (extremely stressful) how stressful they usually think each of the following areas of life is: work, financial concerns, social/community involvements, interpersonal relationships, family, and personal or inner-life concerns.

Results

Stress and Illness Scores

Of the 837 executives who were contacted by mail, 670 (80%) returned completed stress and illness questionnaires. The mean stress score was 399, with a standard deviation of 162, a range from 0 to 2,239, and a median of 306. The mean illness score was 913, with a standard deviation of 1,115, a range from 0 to 6,900, and a median of 550. Comparison of these executives' scores with norms available in the literature (Holmes & Masuda 1974; Wyler et al., 1968, 1970) indicates that on the average, they had experienced a moderate amount of illness (comparable to the threat of life and discomfort associated with having a peptic ulcer or high blood pressure) in the previous 3 years. During this period, they had, on the average, also encountered sufficient change and demands for readjustment in their lives to constitute major life crisis (what Holmes has associated with an 80% likelihood of getting seriously ill in the near future).

A Pearson product-moment correlation of .24 ($p < .025$) was obtained between the total stress and total illness scores. Canonical correlations were also run to determine whether a stronger relationship might be obtained. Stress scores—both the standard weighted scores and simple frequencies—for various areas of life (work, home, community, etc.) were used as the predictor, and illness scores—both weighted and frequencies—for various body systems (cardiovascular, respiratory, etc.) were used as the criterion set. Neither analysis of unweighted stress events and illnesses nor correlations of selected types of stress with selected types of illness, however, significantly strengthened the statistical relationship between stress and illness. The weak, but significant, correlation of .24 is consistent with most of the available research reports (Rabkin & Struening, 1976).

Testing of Group Differences

Completed personality questionnaires were returned by 86% of the high stress/low illness and 75% of the high stress/high illness subjects. Forty "test" subjects were randomly selected from each group for analysis of differences across personality, demographic, and perception variables, and 81 subjects were put aside for cross-validation purposes.

Mean differences between the test subjects of the two groups were evaluated by *t* test. None of the demographic variables and only one of the perception variables yielded significant differences, whereas several of the personality variables did so. Further evaluation of group differences was achieved by a

Table 1

Alienation from self	102.35	117.24	219.15	185.77	3.36**	1.04
Alienation from work	181.67	122.04	223.73	175.09	1.22	.43
Alienation from interpersonal	256.02	162.76	316.10	165.24	1.64	—
Alienation from family	158.47	139.02	198.72	144.33	1.27	—
Alienation from social	202.15	100.21	226.95	133.93	.94	—
Role consistency	29.22	6.42	29.50	6.44	.19	.30
Challenge						
Vegetativeness	155.50	140.24	216.27	160.94	1.98*	.99
Security	21.11	6.33	22.19	8.60	.34	.35
Cognitive structure	13.35	2.81	14.10	2.85	1.10	.21
Adventurousness	269.00	164.58	337.54	174.95	1.78*	—
Endurance	15.97	2.35	14.37	3.19	−.96	—
Interesting experiences	34.97	6.83	32.52	7.02	−.92	
Perception of personal stress	3.00	1.21	3.83	1.73	2.46**	.43

Note. For all variables, the higher the number, the greater the degree of the variable observed. Superior hardiness is indicated by higher scores on achievement, role consistency, endurance, and interesting experiences, and lower scores on nihilism, external locus, powerlessness, dominance, leadership, alienation (from self, work, social institutions, interpersonal relationships, and family), vegetativeness, security, cognitive structure, and adventurousness. A subject's scores on all areas of alienation, measured by the Alienation Test, have a possible range of 0 to 1,200. Vegetativeness, nihilism, powerlessness, and adventurousness scores, also from the Alienation Test, may range from 0 to 1,500. External locus has a low of 0 and an upper limit of 23. The scales taken from the Jackson test—achievement, dominance, cognitive structure, and endurance—have a minimum value of 0 and a maximum of 20. The California Life Goals scale—leadership, security, and interesting experiences—may range from 0 to 60. Role consistency has a low of 0 and a high of 40; perception of personal stress can range from 0 to 7.

[a] $n = 40$.

* $p < .05$.

** $p < .01$.

discriminant function analysis done on all the personality variables plus the one perception variable that yielded a significant *t* score. After all data are transformed into standard scores, discriminant function analysis computes a discriminant equation, or a linear combination of weighted variables that produces the greatest statistically derivable distance between the two groups. The larger the weighting or discriminant coefficient of a variable, the more powerful it is as a group discriminator.

Table 1 presents all variables submitted to discriminant function analysis and their summary statistics, including significance of difference between groups established by *t* test. The results demonstrate that high stress/low illness executives can be distinguished from high stress/high illness subjects. The 11 variables for which a standardized discriminant function coefficient is provided in the table combine to form a significant function, with a Wilks's Lambda of .64, significant at the .001 level, and a canonical correlation of .60. The Wilks's Lambda (see Huberty, 1975) is a measure of the original variable's discrimi-

nant power, before it is removed by the discriminant function. The canonical correlation is a measure of the association between the single discriminant function and the set of dummy variables that defines the two group memberships. Given the composition of this function, the general position concerning hardiness is confirmed. High stress/low illness executives are, at least in some ways, more in control, more committed, and more oriented to challenge than are high stress/high illness executives. Looking at the variables that make the most significant contribution to the discriminant equation and that are also responsible for significant mean differences, the high stress/low illness executives are distinguished by their sense of commitment to (or lack of alienation from) self, their sense of vigorousness (as opposed to vegetativeness) about life, their sense of meaningfulness (as opposed to nihilism), an their internal (as opposed to external) locu of control. One perception-of-stress variabl joins the important personality discrimina tors—high stress/low illness executives fin the personal sphere of their lives significantl less stressful then do the high stress/hig illness subjects.

Several personality variables appear to con tribute to the discriminant equation eve though they do not yield significant mean dif ferences by t test. Although it is risky t interpret the discriminant coefficients of thes variables, it is worth noting that the direc tion of mean difference is in general consisten with the hypotheses concrening hardiness a an insulation against illness.

Along with their analytic function, the dis criminant coefficients also serve a classifica tory and validation purpose. Multiplying a

subject's scores on the discriminating variables by the associated coefficients allows one to predict the likelihood of the subject's membership in each of the groups. As a test of the classificatory power of the derived discriminant equation, its coefficients are (a) reapplied to the test subjects used to derive the equation and (b) applied to the scores of the "holdout" cases. The discriminant function presented in Table 1 shows predictive capability both internally and externally. Applying the unstandardized versions of the discriminant function coefficients to the raw scores used to derive the function, 78% of the "test" cases are correctly classified (80% of the high stress/low illness executives and 75% of the high stress/high illness subjects). This significantly correct ($p < .025$) classification is matched in the external cross-validation. Using the unstandardized coefficients on the raw data from the "holdout" subjects, 35 hits (77%) and 21 hits (60%) in the high stress/low illness and high stress/high illness groups, respectively, are realized ($p < .05$).

These cross-validation results offer support for the stability and generalizibility of the results obtained through discriminant function analysis. An examination of the statistics for the entire sample (test cases plus holdouts), which are notably similar to those of the test cases in Table 1, illustrates the strength of the discriminant analysis. Table 2 presents the mean values, standard deviations, and t values for the full high stress/low illness and high stress/high illness groups.

Discussion

This study of persons who do not fall ill despite considerable stress suggests that personality may have something to do with staying healthy. Using the five most significant discriminators of the high stress/low illness executives (i.e., the variables that contribute to the discriminant equation and produce significant ts) one can speculate on what happens when the hardy individuals meet a stressful life event—how they evaluate the threat posed by the event and cope with it.

A male executive having to deal with a job transfer will serve as an example. Whether hardy or not, the executive will anticipate and experience the changes that the transfer will bring about—learning to cope with new subordinates and supervisors, finding a new home, helping children and wife with a new school and neighborhood, learning new job skills, and so on. The hardy executive will approach the necessary readjustments in his life with (a) a clear sense of his values, goals, and capabilities, and a belief in their importance (*commitment* to rather than *alienation* from *self*) and (b) a strong tendency toward active involvement with his environment (*vigorousness* rather than *vegetativeness*). Hence, the hardy executive does more than passively acquiesce to the job transfer. Rather, he throws himself actively into the new situation, utilizing his inner resources to make it his own. Another important characteristic of the hardy executive is an unshakable sense of meaningfulness and ability to evaluate the impact of a transfer in terms of a general life plan with its established priorities (*meaningfulness* rather than *nihilism*). For him, the job transfer means a change that can be transformed into a potential step in the right direction in his overarching career plan and also provide his family with a developmentally stimulating change. An *internal* (rather than *external*) locus of control allows the hardy executive to greet the transfer with the recognition that although it may have been initiated in an office above him, the actual course it takes is dependent upon how he handles it. For all these reasons, he is not just a victim of a threatening change but an active determinant of the consequences it brings about. In contrast, the executive low in hardiness will react to the transfer with less sense of personal resource, more acquiescence, more encroachments of meaninglessness, and a conviction that the change has been externally determined with no possibility of control on his part. In this context, it is understandable that the hardy executive will also tend to perceive the transfer as less personally stressful than his less hardy counterpart.

The mechanism whereby stressful life events produce illness is presumably physiological. Whatever this physiological response is, the personality characteristics of hardiness may cut into it, decreasing the likelihood of

breakdown into illness. Needless to say, description of the actual nature of physiological mechanisms and their links to personality and stressful occurrences will have to wait for more sophisticated stress research. Until then, however, two alternative explanations of the present results should be considered.

It could be argued that there is a spurious factor at work in the subjects' completion of questionnaires, one that determines what they say about personality, stress levels, and illness experience. Mechanic (1976) has discussed the possible distortion of stress data by a variable that he calls illness behavior. From Mechanic's perspective, one could suggest that the high stress/high illness executives have not really undergone any physiological breakdown but that they simply want to act and be treated as if they are sick and thereby withdraw from a life situation experienced as too stressful. The best evaluation of this position would come from a study that employs physiological rather than self-report measures of illness and monitors physiological states before and after the occurrence of a stressful life event. Until such studies are available, reliance must be placed on data already collected. Mechanic's explanation seems much more likely to apply to the self-report of mild, vague symptoms than to report of more serious illness. For example, headaches and indigestion might well be reported by subjects engaging in illness behavior. But it seems unlikely that definite illnesses requiring medical diagnosis, such as heart attack, cancer, detached retina, and even hypertension would be erroneously reported. Illnesses of the latter sort are responsible for high illness scores on the self-report instrument used in the present study. It is therefore not likely that the results obtained can be explained completely by the concept of illness behavior.

Another alternative explanation would suggest that the observed personality differences between the high stress/low illness and the high stress/high illness executives result from the latter group having experienced illness. Presumably, the high stress/high illness executives were not more alienated, external in beliefs concerning locus of control, and uninterested in change before the illnesses occurred. Their responses to the personality questionnaire may reflect the psychological debilitating effects of illness. A prospective longitudinal study in which stress and personality scores at Time 1 are used to predict illness scores at Time 2 is obviously necessary. But the present study provides some basis for regarding the alternative explanation as less likely than that offered here. Although not discussed in this report, subjects found to be low in stress and high in illness showed personality scores midway between the high stress/low illness and high stress/high illness groups (Kobasa, 1977). It is of specific relevance to the alternative explanation that the low stress/high illness subjects were lower on nihilism, alienation from self, vegetativeness, and external locus of control than were high stress/high illness subjects. This finding indicates that personality questionnaire responses indicative of lack of hardiness are not merely a response to illness.

Continued work in the area of stress is essential. There is still much to be learned about the role of personality and other mediators in the connection between stressful life events and illness or health. Should studies incorporating physiological measures and employing prospective designs confirm the present findings, then instead of merely warning persons to avoid stressful lives, social scientists will be able to illuminate ways of developing the personality characteristics that can aid in a productive and healthy life lived in the full complexity of modern, urbanized, industrialized societies.

Interpersonal Attraction in Exchange and Communal Relationships

Margaret S. Clark
Carnegie-Mellon University

Judson Mills
University of Maryland

Communal relationships, in which the giving of a benefit in response to a need for the benefit is appropriate, are distinguished from exchange relationships, in which the giving of a benefit in response to the receipt of a benefit is appropriate. Based on this distinction, it was hypothesized that the receipt of a benefit after the person has been benefited leads to greater attraction when an exchange relationship is preferred and decreases attraction when a communal relationship is desired. These hypotheses were supported in Experiment 1, which used male subjects. Experiment 2, which used a different manipulation of exchange versus communal relationships and female subjects, supported the hypotheses that (a) a request for a benefit after the person is aided by the other leads to greater attraction when an exchange relationship is expected and decreases attraction when a communal relationship is expected, and (b) a request for a benefit in the absence of prior aid from the other decreases attraction when an exchange relationship is expected.

This research is concerned with how the effects of receiving a benefit and a request for a benefit differ depending on the type of relationship one has with the other person. Two kinds of relationships in which persons give benefits to one another are distinguished, exchange relationships and communal relationships. The stimulus for this distinction was Erving Goffman's (1961, pp. 275–276) differentiation between social and economic exchange.

In the present theorizing, the term *exchange relationship* is used in place of Goffman's term *economic exchange* because many of the benefits that people give and receive do not involve money or things for which a monetary value can be calculated. A benefit can be anything a person can choose to give to another person that is of use to the person receiving it.[1]

In an exchange relationship, members assume that benefits are given with the expectation of receiving a benefit in return. The receipt of a benefit incurs a debt or obligation to return a comparable benefit. Each person is concerned with how much he or she receives in exchange for benefiting the other and how much is owed the other for the benefits received.

Since all relationships in which persons give and receive benefits are social, another term is needed to describe relationships in which each person has a concern for the welfare of the other. The term *communal* seems to be the most appropriate. The typical relationship between family members exemplifies this type

This research was supported by a grant from the National Science Foundation.

[1] Benefits are not the same as rewards, when the term *rewards* refers to "the pleasures, satisfactions, and gratifications the person enjoys" (Thibaut & Kelley, 1959, p. 12). The receipt of a benefit usually constitutes a reward, however rewards occur for reasons other than the receipt of a benefit. For example, the rewards that a parent receives from a newborn infant would not fall within the definition of a benefit, since the infant does not choose to give them to the parent. The present theorizing is not concerned with "dependent" relationships in which one person receives benefits from another but does not give benefits to the other.

Copyright 1979 by the American Psychological Association, Inc. 0022-3514/79/3701-0012$00.75

of relationship. Although it might appear to an observer that there is an exchange of benefits in communal relationships, the rules concerning giving and receiving benefits are different than in exchange relationships.

Members of a communal relationship assume that each is concerned about the welfare of the other. They have a positive attitude toward benefiting the other when a need for the benefit exists. They follow what Pruitt (1972) has labeled "the norm of mutual responsiveness." This rule may create what appears to an observer to be an exchange of benefits, but it is distinct from the rule that governs exchange relationships whereby the receipt of a benefit must be reciprocated by the giving of a comparable benefit. The rules concerning the giving and receiving of benefits are what distinguish communal and exchange relationships, rather than the specific benefits that are given and received.

From the perspective of the participants in a communal relationship, the benefits given and received are not part of an exchange. The attribution of motivation for the giving of benefits is different from that in an exchange relationship. In a communal relationship, the receipt of a benefit does not create a specific debt or obligation to return a comparable benefit, nor does it alter the general obligation that the members have to aid the other when the other has a need. In a communal relationship, the idea that a benefit is given in response to a benefit that was received is compromising, because it calls into question the assumption that each member responds to the needs of the other.

Experiment 1

The first study reported here was based on the assumption, similar to that made by Kiesler (1966) in her study of the effect of perceived role requirements on reactions to favor-doing, that the giving of a benefit will decrease attraction if it is inappropriate for the type of relationship one has with the other. A benefit given in response to a benefit received in the past or expected in the future is appropriate in an exchange relationship but is inappropriate in a communal relationship. A benefit given specifically because it fulfills a need is appropriate in a communal relationship but not in an exchange relationship.

If two people have an exchange relationship and one person benefits the other, it is appropriate for the other to give the person a comparable benefit. The receipt of a benefit under these circumstances should lead to greater attraction. On the other hand, if two people have a communal relationship and one person benefits the other, it is inappropriate for the other to give the person a comparable benefit, since it leaves the impression that the benefit was given in response to the benefit received previously. The other is treating the relationship in terms of exchange, which is inappropriate in a communal relationship.

When a communal relationship does not yet exist but is desired, the receipt of a benefit should have the same effect as when a communal relationship is assumed to exist. A benefit from the other after the other has been benefited should reduce attraction if there is a desire for a communal relationship with the other. If an exchange relationship is preferred, the receipt of a benefit after the other is benefited should result in greater attraction. Experiment 1 was conducted to test these hypotheses.

The predictions concerning communal relationships might seem contrary to what would be expected from equity theory (Adams, 1963). On the basis of equity theory, one might expect that a benefit from another following aid to that other would increase liking in *any* relationship, because it would reduce inequity. However, the predictions are not inconsistent with a recent discussion of equity theory (Walster, Walster, & Berscheid, 1978). According to Walster, Walster, and Berscheid:

> Another characteristic of intimate relationships, which may add complexity, is that intimates, through identification with and empathy for their partners, come to define themselves as a *unit*; as *one* couple. They see themselves not merely as individuals interacting with others, but also as part of a partnership, interacting with other individuals, partnerships, and groups. This characteristic may have a dramatic impact on intimates' perceptions of what is and is not equitable. (pp. 152–153)

In Experiment 1 the desire for a communal relationship was manipulated by using un-

married males as the subjects and having the part of the other played by an attractive woman, who was described as either married or unmarried. It was assumed that people desire communal relationships with attractive others, but only with those available for such relationships. It was further assumed that the unmarried woman would be considered available for a communal relationship, whereas the married woman would not. Thus, it was assumed that the male subjects would desire a communal relationship with the attractive, unmarried woman but would prefer an exchange relationship with the attractive, married woman.

Method

Overview. Under the guise of a study of task performance, unmarried male college students worked on a task while a television monitor showed an attractive woman working on a similar task in another room. When the subject completed the task, he was awarded 1 point toward extra credit for finishing on time and given the opportunity to send some of his excess materials to the other, who supposedly had a more difficult task. Following receipt of the aid, the other completed her task and was awarded 4 points. Some of the subjects received a note from the other that thanked them (no-benefit conditions), whereas some received a note from the other that thanked them and gave them one of her points (benefit conditions). After receiving the note, the subjects were given information indicating that the other was either married (exchange conditions) or unmarried (communal conditions). Shortly thereafter, liking for the other and expectations concerning a future discussion with the other were assessed.

Subjects. The subjects were 96 unmarried, male students in introductory psychology courses who participated in order to earn extra course credit. They were randomly assigned to one of the four experimental conditions: exchange–benefit, exchange–no benefit, communal–benefit, communal–no benefit.

Procedure. Upon arriving for the experiment, the subject was greeted by the experimenter and told that another subject had already arrived and was in an adjacent room. The subject was seated so that he could see a video monitor that showed an attractive female. The experimenter mentioned that the person appearing on the monitor was the other subject, Tricia. The experimenter told the subject that before starting she would explain some things about the studies in which the subject would be participating, which she had already mentioned to Tricia.

The experimenter said that the first study was actually one of two she would ask them to participate in that day. Each of the two studies took less than half an hour. Although the studies were unrelated, she was asking people to participate in both of them during one session. The first study involved having both subjects work on a vocabulary task. She suspected that people's approaches to solving this task varied when certain conditions were changed. In the condition to which he and Tricia had been randomly assigned, they would be able to see each other over closed-circuit television but not be able to talk to each other directly. To enhance credibility, there was a portable television camera in the room pointing at the subject. Through the use of videotape, what appeared on the monitor was the same for every subject. When the subject asked why he was watching the other person on the monitor, which typically happened, he was told that in the past it had been found that when people worked separately on these tasks in the same room their performance was often affected by the presence of the other person. This might have happened because people could talk to one another or because they could see one another, and the experiment was designed to separate those variables.

The experimenter explained that the second study would be quite different from the first, since it would involve much more contact with the other person. She would bring both participants into one room and ask them to talk over things that they had in common. She was interested in the way in which holding common interests helped people to get to know one another. The experimenter mentioned that in the past, people who had participated had sometimes gotten to know each other quite well.

Vocabulary task. The experimenter next pointed to a batch of letters printed on small cards in front of the subject and said that his task in the first study was to form 10 different four-letter words from the letters. She went on to say that there were two versions of this task and one was more difficult than the other. She had flipped a coin to determine which task each of them would be working on, and the subject would have the easier one, while Tricia would have the more difficult one. The subject's task was easier because he had 55 letters ranging from A to Z, whereas Tricia had only 45 letters ranging from A to L. The subject was to time himself on the task with a stopwatch. Although he and Tricia were not permitted to speak to each other directly, one type of communication was permitted: They would be allowed to send and request letters. Simple forms were available for this purpose. The experimenter would come into the room from time to time to see if the subject had any messages he wanted to send and would deliver them for him.

The experimenter explained that time was a factor in the first study and that an individual's motivation to do well on a task would obviously affect the time taken to complete the task. Therefore, she was taking precautions to insure that motivation to do well was kept at a high level. She would award points toward a possible extra credit for finishing the task in a minimum amount of time. The subjects were not told exactly what that amount of time would be or how the conversion to credit would be made, but just to finish as quickly as they could. The experimenter mentioned that the award-

ing of points to maintain motivation would obviously not be necessary in the second study.

The subject was told to start his stopwatch, begin working, and stop the watch when he had finished. The experimenter picked up another stopwatch and left, saying she would give Tricia the watch and start her on her task. The 55 letters that the subject had to work with allowed him to complete the task within 10 minutes. When approximately 10 minutes had elapsed, the experimenter returned and asked if the subject had any letters he wanted to send to Tricia. All subjects gave the experimenter some letters for Tricia. At this point, the experimenter looked at the subject's stopwatch and told him that he had finished the task in time to get 1 point toward extra credit. As she did so, she also filled out a form indicating the time the subject had taken to complete the task and that he had earned 1 point. She explained that if Tricia finished her task in time she would earn 4 points, since her task was more difficult. The experimenter went on to say that since she allowed participants in the study to send and request letters, she also allowed them to share points they earned. Thus, Tricia could send the subject some of her points if she wanted to do so. The experimenter left the room saying she would give Tricia the letters. Tricia continued to work on her task for about 5 minutes and then finished. The experimenter handed Tricia a form similar to that given the subject earlier. Tricia smiled, wrote a note on a slip of paper, folded it, and gave it to the experimenter.

Benefit manipulation. Within a few moments, the experimenter returned to the subject's room and turned off the monitor. She mentioned that Tricia had completed her task within the necessary time and had received 4 points. She handed the subject a folded note that she said Tricia had asked be given to him. In the no benefit condition, the note said, "Thanks for sending the letters." In the benefit conditions, the note said, "Thanks for sending the letters. The experimenter said it would be OK to give you one of my points. She said she would add it onto the points you've already earned before the end of today's session." Which message the note contained was unknown to the experimenter at the time she handed it to the subject. This was accomplished by having the experimenter pick the note out of a container of folded notes of both types.

Relationship manipulation. The experimenter told the subject that there was one more thing to be done before getting on to the next study. She said she was going to give Tricia some questionnaires to fill out and would then get some more forms for the subject. In the exchange conditions, the experimenter said:

> Tricia is anxious to get on to the next part of the study, since she thinks it will be interesting. Her husband is coming to pick her up in about half an hour and she wants to finish before then.

In the communal conditions, she said:

> Tricia is anxious to get on to the next part of the study, since she thinks it will be interesting. She's new at the university and doesn't know many people. She has to be at the administration building in about half an hour and she wants to finish before then.

Dependent measures. The experimenter then left the room for approximately 5 minutes. When she reappeared she brought two forms, mentioning that these were the forms she had told the subject about. She reminded the subject that the second study involved having the participants talk over things they had in common with each other. She said that before starting it was necessary to get some idea of what their expectations were in order to control for them, since they would vary from person to person. The subject was asked to fill out a form indicating what he expected the interaction would be like and, in addition, another form indicating what his first impressions of the other person were. The experimenter said that these forms would be kept completely confidential and left the room while they were filled out.

The first-impressions form, which was given to the subject on top of the form concerning expectations about the discussion, asked him to rate how well 11 traits applied to the other, on a scale from 0 (extremely inappropriate) to 20 (extremely appropriate). The traits were *considerate, friendly, insincere, intelligent, irritating, kind, open-minded, sympathetic, understanding, unpleasant,* and *warm.* The subject was also asked to indicate his degree of liking for the other, on a scale from 0 (dislike very much) to 20 (like very much). The other form asked the subject to indicate how friendly, spontaneous, relaxed, enjoyable, and smooth he expected the discussion to be, on scales from 0 to 20.

Suspicion check. After the subject had completed both forms, the experimenter casually mentioned that there was something more to the study and asked whether the subject had any idea what it might be. The responses of eight persons indicated suspicion of the instructions, and they were not included as subjects. Four persons thought the experiment was designed to test reactions to the note, one thought the points might have something to do with the ratings, two thought Tricia was a part of the experiment, and one questioned whether Tricia was actually married. Four of these persons were run under the exchange–benefit condition, two under the exchange–no-benefit condition, one under the communal–benefit condition, and one under the communal–no-benefit condition. In addition, 12 other persons were not included as subjects. Six could not finish the task within the 10 minutes allowed, one did not read the note before filling out the forms, two failed to follow instructions when filling out the forms, one discovered the concealed videotape recorder beneath the monitor, and two were married.

Finally, the true purpose of the experiment was fully explained, and the subject promised not to discuss it with anyone.

Results

A measure of liking for the other was calculated by summing the scores for each of the 11 traits and the direct measure of liking on the impressions questionnaire. The scores for the favorable traits and for the direct rating of liking were the same as the subject's ratings. The scores for the unfavorable traits were obtained by subtracting the subject's ratings for those characteristics from 20. The means for the experimental conditions for the measure of liking are presented in Table 1.

From the hypotheses, it would be expected that the scores on the measure of liking would be greater in the exchange–benefit condition than in the exchange–no-benefit condition and would be lower in the communal–benefit condition than in the communal–no-benefit condition. From Table 1 it can be seen that the results are in line with the predictions. An analysis of variance of the measure of liking revealed that the interaction between type of relationship and benefit was significant, $F(1, 92) = 8.35$, $p < .01$. Neither of the main effects approached significance. A planned comparison indicated that the difference between the exchange–benefit condition and the exchange–no-benefit condition was significant, $F(1, 92) = 4.17$, $p < .05$. A second planned comparison indicated that the difference between the communal–benefit condition and the communal–no-benefit condition was also significant, $F(1, 92) = 4.37$, $p < .05$.

A measure of anticipated pleasantness of the discussion was calculated by summing the ratings for the questions concerning how friendly, spontaneous, relaxed, enjoyable, and smooth the subjects expected the discussion to be. As expected, the means for this measure were greater for the exchange–benefit condition than for the exchange–no-benefit condition and were lower for the communal–benefit condition than for the communal–no-benefit condition. However, the interaction between the type of relationship and benefit was not significant. The main effects were also not significant.

Table 1
Means for the Measure of Liking in Experiment 1

Relationship	Benefit from the other: Benefit	Benefit from the other: No benefit
Exchange	193	176
Communal	177	194

Note. The higher the score, the greater the liking. Scores could range from 0 to 240. $n = 24$ per cell.

Discussion

The results of Experiment 1 provide support for the hypothesis that when a communal relationship is desired, a benefit following prior aid decreases attraction. When the attractive woman they had aided was unmarried (communal conditions), the unmarried male subjects liked her less when she gave them a benefit than when she did not. When the attractive woman who was aided turned out to be married (exchange conditions), she was liked more when she gave the subject a benefit than when she did not. The results for the married woman are consistent with the hypothesis that the receipt of a benefit after the other is benefited leads to greater attraction when an exchange relationship is preferred.

It might be thought that the lower liking of the unmarried woman in the benefit condition than in the no-benefit condition could be explained by a difference in the anticipation of future interaction, a variable which has been shown to influence liking in previous research (Darley & Berscheid, 1967; Mirels & Mills, 1964). Such an interpretation would make the assumption that the repayment by the unmarried woman with whom the subject wished to interact suggested that she did not wish to interact with him. However, this assumption is reasonable only if the future interaction is of the kind referred to here as a communal relationship.

If the future interaction involved an explicit exchange of benefits, there is no reason the repayment would have suggested that the unmarried women did not wish to interact with the subject. Since an interpretation in terms of the anticipation of future interaction requires a distinction between different types of interaction similar to the distinction between communal and exchange relationships, it is not an alternative explanation but essentially the same interpretation in somewhat different language.

A different interpretation might be suggested that has to do with the role relationships of males and females. It might be argued that the male subjects subscribed to a "traditional" rule that males should give gifts to females, who should gracefully accept them and not attempt to repay their benefactor, and the unmarried woman who gave them a point violated this rule. Such an interpretation would assume that the males did not apply the same rule to their relationships with a woman who is married, which does not seem consistent with traditional values concerning the role of men vis-à-vis women. If the interpretation is restricted to the relation of men and women in romantic relationships, then it is not an alternative explanation, since romantic relationships are communal relationships.

That the desire for a communal relationship was induced by creating a situation in which there was a possibility of a romantic relationship with an attractive member of the opposite sex was not fortuitous. A romantic relationship that might lead to the development of a family relationship through marriage is a particularly appropriate situation for the study of communal relationships, since relationships between family members are the most typical kind of communal relationships. However, the distinction between communal and exchange relationships is not restricted to romantic relationships with members of the opposite sex. The same effect should occur in situations in which a communal relationship, such as friendship, is desired or expected with a member of the same sex.

It was assumed not only that the other was perceived as available for a communal relationship in the communal conditions but also that she was regarded as an attractive partner for such a relationship. If the other is unattractive, a communal relationship with her should not be desired even if she is available for such a relationship. People do not desire communal relationships with people they dislike. An exchange relationship should be preferred with an unattractive other, and thus a benefit from such a person after he or she has been aided should lead to greater attraction.

Since the effect found in the first study involves the assumption that the benefit that the person received from the other is perceived as a response to the previous benefit that the other received, it should not occur if the other had not received something of value from the person. The receipt of a benefit when the other has not been aided previously should lead to greater liking when a communal relationship is expected or desired. The rule in communal relationships is to respond to a need rather than to reciprocate benefits. The giving of a benefit when no prior help has been received is appropriate for a communal relationship if there is or might be a need for the benefit.

Some evidence that the receipt of a benefit when the other is not aided previously produces greater liking when there is a communal relationship than when there is not is provided by the study by Kiesler (1966). She found that a partner on a cooperative task was liked more when he shared his winnings with the subject than when he did not share, whereas an opponent on a competitive task was liked about the same when he shared and did not share. Partnership on a cooperative task should create the expectation of a communal relationship, and in Kiesler's study the subject always lost, so the partner did not receive any aid from the subject prior to benefiting the subject. However, the possibility that the subject's losing could have been construed as a kind of aid for his opponent in the competitive conditions complicates the comparison of the cooperative and competitive conditions of Kiesler's study.

Experiment 2

The distinction between communal and exchange relationships also has implications for reactions to a request for a benefit. If it is true that in an exchange relationship any benefit given by one member to the other creates a debt or obligation to return a comparable benefit, a request for a benefit from another after one has been given aid by that other creates an opportunity to repay the debt. Thus, such a request following aid should be appropriate in an exchange relationship. Since it provides an opportunity to eliminate any tension caused by the presence of the debt, it should increase liking for the other.

The idea that the recipient of a benefit will like his or her benefactor more if he or she can return the benefit has been expressed before (Mauss, 1954). Several studies have shown that recipients of benefits like the donor more if they are able to repay the benefit than if they are not able to repay, whether the opportunity is provided by the donor's specifically requesting that the other repay the benefit (Gergen, Ellsworth, Maslach, & Seipel, 1975) or whether the opportunity to repay is provided but repayment is not specifically asked for (Castro, 1974; Gross & Latané, 1974).

In a communal relationship, to request a benefit after having given another person aid is inappropriate. It may imply that the original aid was not given with the intent of satisfying a need but rather with the expectation of receiving something in return, which may be taken as an indication that the other does not desire involvement in a communal relationship. Assuming that beginning or maintaining a communal relationship with another is desirable, such an implication should be frustrating and therefore result in decreased liking.

If one has not been previously aided by another and there is no opportunity to aid the other in the future, a request from that other is inappropriate in an exchange relationship. In an exchange relationship, a person who has not been aided by another should like the other more when he or she does not ask for a benefit than when he or she does ask for a benefit.

However, requesting a benefit in the absence of prior aid is appropriate in a communal relationship. Such a request implies that the other desires a communal relationship and, assuming that beginning or maintaining such a relationship is desirable, it should result in increased liking. Jones and Wortman (1973) suggest that asking another for a benefit is a way of conveying that we think highly of them. They say, "This tactic is likely to convey that we feel good about our relationship with the target person, since it is not customary to ask people to do favors for us unless our relationship is a relatively good one" (Jones & Wortman, 1973, p. 13).

The implications of the distinction between communal and exchange relationships for reactions to requests for a benefit in the context of prior aid or lack of prior aid were investigated in Experiment 2. A situation was arranged in which aid could be given to the subject and, later, a different benefit requested from the subject. The anticipation of a communal relationship was created by leading the subject to believe that the other wanted to meet people and that she would be discussing common interests with the other. The anticipation of an exchange relationship was created by not mentioning anything about the other wanting to meet people, implying that the other was very busy and leading the subject to believe that she would be discussing differences in interests with the other.

The following hypotheses were tested in the second experiment:

1. A request for a benefit from another after the person is aided by the other leads to greater attraction when an exchange relationship is expected.

2. When a communal relationship is expected, a request for a benefit after the person is aided by the other decreases attraction.

3. A request for a benefit in the absence of aid from the other decreases attraction when an exchange relationship is expected.

4. When a communal relationship is expected, a request for a benefit in the absence of aid from the other increases attraction.

Method

Overview. Under the guise of a study of task performance, female college students worked on a task while a television monitor showed another female working on a similar task in another room. Some of the subjects were told that the other was married, had a child, and lived far from the university, and that she and the subject would be discussing differences in interests in a second study (exchange conditions). Other subjects were told that the other was new at the university and did not know many people, and that she and the subject would be discussing common interests in a second study (communal conditions). The other female finished the task, received 1 point, and gave the subject aid on her supposedly more difficult task or did not give the subject aid. The other female then requested a point from the subject or did not request a point. Finally, the subject's liking for the other and expectations concerning the future discussion with the other were assessed.

Subjects. The subjects were 80 female, introductory psychology students who received extra credit toward their course grade for their participation. They were randomly assigned to one of the eight experimental conditions: exchange-aid-request, exchange-aid-no request, exchange-no aid-request, exchange-no aid-no request, communal-aid-request, communal-aid-no request, communal-no aid-request, and communal-no aid-no request.

Procedure. Upon arriving for the study, the subject was greeted by the experimenter and told that the other subject scheduled to participate at the same time had already arrived and was waiting in another room for the experiment to begin. The experimenter explained that it would take a little time for the equipment to warm up before the experiment could begin.

Relationship manipulation. In the communal conditions, the experimenter casually stated that the other person was anxious to begin because:

> She thinks it will be interesting. She's new at the university, doesn't know many people, and she's interested in getting to know people.

In the exchange conditions, the experimenter casually said:

> She wants to finish soon. Her husband is coming by to pick her up, then they have to pick up her child and go home to Columbia (a city some distance from the university).

The experimenter said that the first study was actually one of two short, unrelated studies they would be asked to participate in that day. The rationale for the first study was the same as in Experiment 1. The experimenter went on to say that the second study would be quite different from the first. In the communal conditions she continued:

> What we're going to do is bring you both into one room. We want you to talk over common interests. We're interested in finding out how people get to know one another. We try to create a relaxed atmosphere, and actually, in the past we've found that some of the people have gotten to know one another quite well.

In the exchange conditions she continued:

> What we're going to do is bring you both into one room. We want you to talk over differences in interests. We're doing this because most people avoid talking about differences in interests and we're interested in getting people's reactions to doing so.

Vocabulary task. After the subject had signed an experimental consent form, the procedure for the vocabulary task was explained in the same manner as in Experiment 1, except that the subject was told that she would be performing the more difficult task while the other person would be performing the easier task. The experimenter pointed out that since the subject's task was the more difficult one, she would have a chance to earn 4 points toward the extra credit, whereas the other person, Tricia, only had a chance to earn 1 point, since she had the easier task. As in Experiment 1, the experimenter mentioned that the awarding of points to maintain motivation obviously would not be necessary in the second study.

After the same instructions concerning the stopwatches as in Experiment 1, the subject was left alone to work on the task for a short time. With the 45 letters the subject had it was impossible for her to finish the task in that time. Subjects typically finished between five and seven words. During the time the subject was working, the experimenter, who always wore a lab coat so that changes in clothing over days could not be detected, could be seen on the monitor starting Tricia on her task and then leaving the room. Tricia finished her task easily. After a short time the experimenter reentered the other room, and Tricia could be seen pushing some extra letters to the front of the table. At this point the experimenter stepped in front of the camera, blocking the subject's view of the other so that the subject could not see whether the other handed the letters to the experimenter. Finally, the experimenter could be seen leaving the room, and Tricia sat back in her chair.

Aid manipulation. Shortly thereafter, the experimenter reentered the subject's room and said that Tricia had finished her task and received 1 point. The experimenter turned off the monitor, commenting that it wouldn't be needed any more. In the aid conditions she said, "Tricia asked me to give you these letters," and handed the subject some letters. In the no-aid conditions there was no mention of the letters. The experimenter then left the room, telling the subject she would be back

Table 2
Means for the Measure of Liking in Experiment 2

Relationship	Aid from & request for benefit from the other: Aid–request	Aid–no request	No aid–request	No aid–no request
Exchange	173	149	149	173
Communal	156	191	179	177

Note. The higher the score, the greater the liking. Scores could range from 0 to 240. $n = 10$ per cell.

shortly. In approximately 3 minutes, she returned, and regardless of whether the subject had finished (none in the no-aid conditions did, whereas most in the aid conditions did), she told the subject she had done well enough to receive the 4 points toward extra credit. She filled out a form indicating this and handed it to the subject. The experimenter said that was all there was to the first study, except for filling out a form if the subject wanted to request any points from Tricia. Before the subject had an opportunity to look at the form, the experimenter said she would check with Tricia and see if she wanted to fill out a form and left the room for approximately 2 minutes.

Request manipulation. When she appeared, the experimenter handed the subject a folded note, supposedly from Tricia, in which a box was checked indicating either that she wished to request 1 point from the subject (request conditions) or that she did not wish to request any points (no-request conditions). The experimenter was unaware of how the form was checked, having drawn it from a container of folded forms checked in both ways. If the subject wished to fill out a form to request points from the other, the experimenter took it.

Dependent measures. Next, the experimenter reminded the subject that the second study would involve having both subjects talk over common interests (communal conditions) or differences in interests (exchange conditions). Before starting the study it was necessary to get some idea of what their expectations were about the forthcoming interaction in order to control for those expectations, since they might vary from person to person. Therefore, she was asking the subject to fill out two forms indicating what her first impressions of the other person were and also what she expected the discussion to be like. The subject was told that these forms would be kept completely confidential.

The first-impressions form, which was given the subject on top of the form concerning expectations about this discussion, was the same as the first-impression form used in Experiment 1. The other form asked the subject to indicate how friendly, spontaneous, strained, enjoyable, and awkward she expected the discussion to be, on scales from 1 to 20.

Suspicion check. The experimenter left and watched through a one-way mirror until she could see that the subject had finished the forms. She then waited approximately 30 additional sec and reentered the room. As she picked up the forms, she casually said that there was something more to the study than she had mentioned before and asked the subject if she had any idea of what it might be. The responses of eight persons indicated suspicion of the instructions, and they were not included as subjects. Five persons suspected that the other person was not actually in the other room, one thought that the other's task had been intentionally made easy, one thought that the request did not actually come from the other person, and one thought that neither the aid nor the request came from the other person. All five people who suspected that the other person was not actually in the other room had been in another study by a different experimenter, in which they were told that another person participated but later found out that there was no such other person. Three of the eight persons were run under the exchange-aid-request condition, two under the exchange-aid-no-request condition, one under the exchange-no-aid-request condition, one under the communal-aid-request condition, and one under the communal-aid-no-request condition. In addition, four other people were not included as subjects. Two requested points from the other person, one did not read the request for a point before filling out the questionnaires, and one asked so many questions that the experimenter could not leave the room before appearing on the monitor.

Finally, the true purpose of the experiment was fully explained, and the subject promised not to discuss it with anyone.

Results

A measure of liking for the other was calculated in the same way as in Experiment 1. The means for the experimental conditions for the measure of liking are presented in Table 2. An analysis of variance of the measure of liking revealed that the main effect of type of relationship was significant, $F(1, 72) = 6.21$, $p < .05$. Neither of the other main effects nor any of the two-way interactions were significant. The three-way interaction between type of relationship, aid, and request was significant, $F(1, 72) = 12.73$, $p < .001$.

From the first hypothesis, it would be expected that scores on the measure of liking would be greater in the exchange–aid–request condition than in the exchange–aid–no-request condition. As can be seen in Table 2, the difference was in the predicted direction. A planned comparison indicated that this dif-

ference was significant, $F(1, 72) = 4.03$, $p < .05$.

From the second hypothesis, it would be expected that liking would be less in the communal–aid–request condition than in the communal–aid–no-request condition. As can be seen in Table 2, the difference was as predicted. A planned comparison indicated that this difference was significant, $F(1, 72) = 8.60$, $p < .01$.

From the third hypothesis, it would be expected that liking would be less in the exchange–no-aid–request condition than in the exchange–no-aid–no-request condition. As can be seen in Table 2, the difference was as predicted. A planned comparison indicated that this difference was significant, $F(1, 72) = 4.07$, $p < .05$.

From the fourth hypothesis, it would be expected that liking would be greater in the communal–no-aid–request condition than in the communal–no-aid–no-request condition. As can be seen in Table 2, the means for these two conditions were very similar. A planned comparison indicated that the difference between these two means was not significant.

Another way of looking at the results is to compare the aid and the no-aid conditions. It would be expected that liking would be greater in the exchange–aid–request condition than in the exchange–no-aid–request condition. As can be seen in Table 2, this expected difference was obtained. A planned comparison indicated that the difference was significant, $F(1, 72) = 3.99$, $p < .05$. It would be expected that liking would be less in the communal–aid–request condition than in the communal–no-aid–request condition. As can be seen in Table 2, this expected difference was obtained. A planned comparison indicated that the difference was marginally significant, $F(1, 72) = 3.93$, $p < .06$. It would be expected that liking would be less in the exchange–aid–no-request condition than in the exchange–no-aid–no-request condition. As can be seen in Table 2, this expected difference was obtained. A planned comparison indicated that it was significant, $F(1, 72) = 4.10$, $p < .05$. Finally, it would be expected that liking would be greater in the communal–aid–no-request condition than in the communal–no-aid–no-request condition. Although the means were in the expected direction, the planned comparison indicated that this difference was not significant.

Table 3
Means for the Measure of Anticipated Pleasantness of the Discussion in Experiment 2

Relationship	Aid from & request for benefit from the other			
	Aid–request	Aid–no request	No aid–request	No aid–no request
Exchange	56	59	58	59
Communal	63	72	70	52

Note. The higher the score, the more positive the subjects' expectations for the discussion. Scores could range from 5 to 100. $n = 10$ per cell.

A measure of anticipated pleasantness of the discussion was calculated by summing the scores on the questions concerning how friendly, spontaneous, strained, enjoyable, and awkward the subjects expected the discussion to be. The scores for the favorable characteristics were the same as the subjects' ratings. The scores for the unfavorable characteristics were obtained by subtracting the subjects' ratings for those characteristics from 21. The means for the experimental conditions for the measure of anticipated pleasantness of the discussion are presented in Table 3.

An analysis of variance of the measure of anticipated pleasantness of the discussion revealed that the main effect of type of relationship was significant, $F(1, 72) = 5.01$, $p < .05$. The main effects of aid and of request and the interactions between type of relationship and aid and between type of relationship and request were not significant. The interaction between aid and request was significant, $F(1, 72) = 7.31$, $p < .01$, and the three-way interaction between type of relationship, aid, and request was also significant, $F(1, 72) = 5.61$, $p < .05$.

As can be seen in Table 3, anticipated pleasantness was approximately the same in all four of the exchange conditions, but there were differences within the communal conditions. Anticipated pleasantness was lower in the communal–aid–request condition than in

the communal–aid–no-request condition. A simple comparison indicated that this difference approached significance, $F(1, 72) = 2.99$, $p < .10$. Anticipated pleasantness was greater in the communal–no aid–request condition than in the communal–no-aid–no-request condition. A simple comparison of this difference was significant, $F(1, 72) = 11.19$, $p < .001$.

Discussion

In general, the results supported the hypotheses concerning reactions to a request for a benefit based on the distinction between communal and exchange relationships. As expected from the hypothesis that a request for a benefit after the person is aided by the other leads to greater attraction when an exchange relationship is expected, it was found that liking for the other was higher in the exchange–aid–request condition than in the exchange–aid–no-request condition. As predicted from the hypothesis that a request for a benefit after the person is aided decreases attraction when a communal relationship is expected, liking was lower in the communal–aid–request condition than in the communal–aid–no-request condition. In line with the hypothesis that a request for a benefit in the absence of aid from the other decreases attraction when an exchange relationship is expected, liking for the other was lower in the exchange–no-aid–request condition than in the exchange–no-aid–no-request condition.

The hypothesis that a request for a benefit in the absence of aid from the other increases attraction when a communal relationship is expected was not supported; there was no difference in liking between the communal–no-aid–request condition and the communal–no-aid–no-request condition. The subjects in the communal–no-aid–request condition may have been somewhat uncertain about the intentions of the other. Although the request may have indicated to the subject that the other wanted a communal relationship with her and consequently led the subject to expect such a relationship, it also may have reminded the subject that the other had not given her aid earlier. This reminder may have raised doubt about whether the other would behave in an appropriate way for a communal relationship. This could explain why the request did not result in increased liking for the other in the communal–no-aid–request condition.

As would be expected from the distinction between communal and exchange relationships, liking was greater in the exchange–aid–request condition than in the exchange–no-aid–request condition, marginally less in the communal–aid–request condition than in the communal–no-aid–request condition, and less in the exchange–aid–no-request condition than in the exchange–no aid–no-request condition. The greater liking in the exchange–aid–request condition than in the exchange–no-aid–request condition could be due to a general tendency for aid to increase liking, as well as to the appropriateness of the request. However, the fact that liking was less in the exchange–aid–no-request condition than in the exchange–no-aid–no-request condition is opposite to what would be expected from a general tendency for aid to increase liking, but follows from the idea that differences in liking are due to the appropriateness of the other's behavior for the type of relationship. That liking was less in the communal–aid–request condition than in the communal–no-aid–request condition is also opposite to the tendency for aid to increase liking and consistent with the effect on liking of the appropriateness of the other's behavior for the type of relationship.

Since the focus was on the interactive effects of type of relationship, a main effect of type of relationship was not specifically predicted. However, the significant main effect that was obtained for liking is understandable in view of the operations used to manipulate type of relationship. Among other things, subjects in the communal conditions may have expected the other to be more similar than did subjects in the exchange conditions.

The results for the measure of anticipated pleasantness of the interaction were also consistent with the distinction between communal and exchange relationships. Anticipated pleasantness was similar in the four exchange conditions, marginally less in the communal–aid–request condition than in the communal–

aid–no-request condition, and greater in the communal–no-aid–request condition than in the communal–no-aid–no-request condition.

The results for the measure of pleasantness can be understood in terms of the assumption that one will anticipate interaction with the other to be more pleasant if one expects a communal relationship than if one expects an exchange relationship. In the exchange condition, subjects were led to expect an exchange relationship by the experimental instructions given in those conditions. Subjects in the communal–aid–request condition should have expected an exchange relationship, because the rules of a communal relationship were violated by the request following the prior aid. Subjects in the communal–no-aid–no-request condition should also have expected an exchange relationship, because the rules of a communal relationship were violated by the other's failure to respond to their needs or to request something from the subject for which the other presumably had a need.

The interpretation of the results for the measure of anticipated pleasantness might appear inconsistent with the fact that liking was not significantly higher in the communal–no-aid–request condition than in the communal–no-aid–no-request condition. However, it is possible that the request for a benefit in the absence of prior aid was sufficient to create an expectation of a communal relationship yet insufficient to increase liking. As mentioned earlier, the request for aid in the communal–no-aid–request condition may have been taken as an indication that the other felt positively toward the subject and thus led the subject to expect a communal relationship with that other, but it may also have reminded the subject that the other had not fulfilled her needs earlier, resulting in ambivalent feelings toward the other.

General Discussion

While it is assumed that the distinction between communal and exchange relationships is made implicitly by most people in their interactions with others, it is not assumed that they are explicitly aware of the distinction or are able to describe how it affects their reactions. Certainly they do not use the terms *communal* and *exchange relationships*. It is also not assumed that everyone makes the distinction in the same way. Some people restrict their communal relationships to only a very few persons, whereas others have communal relationships with a wide circle of others. There are some people who do not make the distinction at all. Some people treat every relationship, even relationships with members of their own immediate family, in terms of exchange.

It is possible for a person to have both a communal relationship and an exchange relationship with the same other, for example, when a person sells something to a friend or hires a family member as an employee. In such instances, a distinction is typically made between what is appropriate for the business (exchange) relationship and what is appropriate for the family or friendship (communal) relationship. Exchange relationships sometimes can develop into communal relationships, such as when a merchant and a customer become close friends or when an employer and an employee marry.

The lack of attention paid to communal relationships in previous research on interpersonal attraction may be accounted for by the fact that almost all of the past research has involved attraction toward persons who are not only previously unknown to the subject but who are not expected by the subject ever to be known in the future. Communal relationships involve an expectation of a long-term relationship, whereas exchange relationships need not be long-term. However, the variables of communal versus exchange relationship and expected length of the relationship are conceptually independent. Exchange relationships may be expected to continue over a long period.

If it is true that treating a communal relationship in terms of exchange compromises the relationship, then exchange theories of interpersonal attraction (e.g., Secord & Backman, 1974, chapter 7) may create a misleading impression about the development and breakup of intimate relationships. The idea that exchange is the basis of intimate relationships may actually have the effect of impairing such relationships. For example, the rec-

ommendation, which seems to be growing in popularity, that prior to marriage a marriage contract be drawn up that specifies in detail what each partner expects from the other, should, if followed, tend to undermine the relationship.

If the theoretical viewpoint of this research is correct, a communal relationship will be strained by dickering about what each of the partners will do for the other. Of course, if one of the partners in a communal relationship is convinced that he or she is being exploited by the other because that person is concerned about the other's welfare while the other is not concerned about his or her welfare, the communal relationship has disintegrated. If this happens in a marriage, there may be attempts to preserve the marriage by changing it into an exchange relationship through dickering.

Person Memory: Personality Traits as Organizing Principles in Memory for Behaviors

Reid Hastie and Purohit Anand Kumar
Harvard University

Subjects studied and recalled sentences describing behaviors while performing a laboratory impression-formation task. Recall was high for behaviors that were incongruent with a personality-trait impression for a character, whereas recall was much lower for behaviors that were congruent or neutral with reference to the impression. Set size, the number of congruent and incongruent behaviors attributed to the character, was shown to be a major determinant of this result. The smaller the size of the incongruent set, the higher the probability of recalling an item from the set. There was no tendency for behaviors to cluster by trait category in recall output protocols. This result was interpreted as evidence that a simple analogy to hierarchical noun categories, studied in many verbal learning experiments on organization of memory, did not apply to the present results. Three theoretical analyses—an associative network model, a depth-of-processing model, and a schema model—are reviewed in light of these results.

Psychologists have been interested for a long time in the effects of abstract organizing principles on memory. Sir Frederic Bartlett's (1932) schema theory is one of the earliest efforts to explicate the relations between an abstract structure and the recall of specific facts. Bartlett proposed that memory is not primarily or literally reduplicative or reproductive. Rather, he argued that perceived events are assimilated to mental schemata that have been formed by similar events experienced in the past. Bartlett's classic treatise on remembering is replete with examples of phenomena that he believed evidenced the workings of these schemata.

Researchers have studied the manner in which experimental subjects use well-defined organizational structures in numerous memory tasks. Miller (1956), Mandler (1967), Tulving (1968), Bower (1970), and Rosch (1973) conducted pioneering research on the operation of semantic structures in the recall of words; Bransford and his colleagues (Bransford & Franks, 1972; Bransford & Johnson, 1973) have studied the operation of linguistic and spatial schemata in recognition and recall; and Kintsch (1974), Thorndyke (1977), and Mandler and Johnson (1977) have studied the operations of schemata in memory for prose paragraphs. One consistent conclusion from these experiments is that recall of specific facts is affected by their relation to an abstract organizing principle, theme, or schema.

Psychologists interested in social judgment have also studied organization—the organization of attitudes and beliefs (Abelson et al., 1968; McGuire, 1968), the perception of social groups (Heider, 1958; Insko, Songer, & McGarvey, 1974), and the organization of impressions (Anderson, 1974b; Hastorf, Schneider, & Polefka, 1970; Rosenberg & Sedlak, 1972a). Recently, researchers have attempted to integrate the two traditions to

This research was supported by National Institute of Mental Health Grant MH-28928 to Harvard University. We would like to thank Joan Dobrof, John Porter, and Barbara Signer for their assistance with the research and David Kenny, Steven Penrod, and Shelley Taylor for comments on this manuscript. Final revision of the manuscript was facilitated considerably by Anthony Greenwald and two anonymous reviewers.

study the manner in which social information is stored and retrieved from memory. Anderson and Hastie (1974), Sulin and Dooling (1974), D'Andrade (1974), Lewis and Anderson (1976), Cantor and Mischel (1977), Markus (1977), Snyder and Uranowitz (1978), and Rogers, Kuiper, and Kirker (1977) have studied the operation of general organizing principles, themes, or prototypes in the perception and memory of information about people. Several of these researchers have suggested that when information is stored in memory about an individual person, personality-trait dimensions or personality prototypes provide the mental categories for the new information. Thus, inferences about abstract personality traits will organize the perception, storage, and retrieval of information about people.

In the three experiments reported in this article, subjects studied and recalled lists of behavior descriptions. The behaviors in each list were attributed to a single fictional character, along with a brief personality-trait sketch. The behavior descriptions were selected to be congruent or incongruent with respect to the personality sketch, and the focus of the experiments was on differential recall of these descriptions.

Differential recall of specific behaviors varying in congruence to the general personality impression would be taken as evidence that the impression controls the encoding, retention, or retrieval of social information. Results from the research cited above imply that information that confirms or is congruent with the impression will be more accurately recalled than information that is incongruent with the impression. Accordingly, our analysis will focus on the relative recall of congruent and incongruent behavior descriptions.

Experiment 1

Method

Design. Each subject studied and recalled sentences from six 20-sentence lists. Each list was comprised of 12 sentences describing behaviors congruent with a personality trait, 4 describing behaviors that were incongruent with the trait, and 4 describing behaviors that were neutral with respect to the trait. The three types of sentences were distributed uniformly across input serial positions. Each of the six lists of behaviors studied by a subject was associated with a different personality trait. There were 12 different traits in the initial set of experimental materials, and so two sets of 6 traits each were arbitrarily created to produce two replications of the design. Finally, each of the 6 subjects studying one of the 6-trait subsets received the 6 traits in a different order. These orders were arranged in a Latin square plan so that each trait occurred in a different within-session position for each subject. This design was replicated with a second set of 12 subjects.

Materials. The memory experiment outlined above required sets of sentences describing behaviors characteristic of a representative sample of personality traits. First, 12 traits were chosen from the 80 traits studied by Rosenberg and Sedlak (1972b): *intelligent–unintelligent, honest–liar, irresponsible–conscientious, friendly–hostile, aggressive–shy,* and *naive–cynical*). The sample was composed of six pairs of "opposite meaning" traits that spanned the space revealed by Rosenberg and Sedlak's multidimensional scaling analysis. The pairs were presented to 12 pretest subjects with an instruction of the form, "Consider a person who is very *intelligent*; you would expect to see him (her). . . ." The resulting lists of pretest subject-generated behaviors were edited to yield 12 three-to-five-word behavior descriptions for each of the traits. Some examples of behaviors generated as congruent with the intelligent trait are "won the chess tournament" and "attended the symphony concert." In addition, the authors generated 48 "neutral" behavior descriptions. These were sentences describing behaviors that were neutral or that had few or no implications about personality. Some examples of neutral behavior descriptions are "ordered a cheeseburger for lunch" and "took the elevator to the third floor." All behavior descriptions were written to describe specific, easy-to-picture events. Finally, four incongruent behaviors were selected for each trait by sampling from the set of behaviors associated with the opposite-meaning trait from each pair (e.g., four behaviors congruent with the unintelligent trait were selected to be incongruent behaviors for the intelligent trait, and so forth). Some examples of incongruent behaviors for the intelligent trait (actually congruent behaviors for the *un*intelligent trait) are "made the same mistake three times" and "was confused by the television show." This list-generation plan provides a control for idiosyncratic characteristics of particular trait-related sentences. For instance, congruent sentences for the intelligent character presented to one subject also appear as incongruent sentences for the unintelligent character presented to another subject.

During the memory task, each list of trait-related behaviors was preceded by an ensemble of eight trait adjectives presented to induce the unitary appropriate personality impression for the list. These adjectives were selected from Anderson's (1968) list of trait terms to be synonymous or close in meaning to the original trait for each list (e.g., for the intelligent list, *intelligent, clever, bright, smart, quick,*

wise, knowledgeable, and *decisive* formed the adjective ensemble). All of the materials were typed on 12.7 cm × 20.3 cm index cards for display to the subjects.

Subjects. The subjects were 24 undergraduate university students. They were paid $1.50 each for their participation in the experiment. Approximately equal numbers of male and female subjects participated in all of the research reported in this article. In no case was there a statistically reliable effect of the sex variable on measures of memory or judgment, and so there will be no further mention of sex differences in this report.

Procedure. The individual experimental sessions lasted approximately 30 minutes. Subjects were told that they would be asked to form impressions and recall information about six fictional characters. On each of the six experimental trials, the subject performed four tasks. First, the subject read aloud the eight trait adjectives that preceded each list. Second, he or she read aloud 20 sentences, presented at a 5-sec-per-sentence rate, describing behaviors performed by the character. Third, the subject recalled as many of the sentences as possible in writing under free-recall instructions. Finally, he or she rated the fictional character's personality on nine bipolar scales. This rating task was included to emphasize the impression-formation task. The results of all rating tasks were consistent with averaging or adding models for impression formation—the more behaviors presented that were congruent with a particular trait, the higher the rating of the stimulus character on that dimension. Beyond this simple finding, results of the rating task were not related to sentence recall, and so they will not be discussed in this article.

Results

The primary data from the experiment are the proportions of behavior descriptions recalled from the congruent, incongruent, and neutral subsets of each list. A note on the scoring method for the behavior descriptions is necessary. The descriptions were simple phrases such as "won the chess tournament," "attended the symphony concert," and so forth. First, a lenient scoring criterion was employed: An item was scored as correctly recalled if the general sense of the description was preserved (i.e., any changes from the original were substitutions of synonymous words). The data reported in this article were tabulated following this criterion. Second, a strict scoring criterion was adopted: An item was scored as correctly recalled if it differed from the original in at most one important word (and if this deviation did not affect the meaning of the phrase). All analyses were repeated with this criterion, and no discrepancies from the present summary were apparent.

Table 1
Mean Proportions of Behavior Descriptions Recalled in Experiment 1

Input serial position	Item type		
	Congruent behaviors	Incongruent behaviors	Neutral behaviors
1 to 5	.47	.57	.38
6 to 10	.33	.48	.36
11 to 15	.35	.47	.27
16 to 20	.60	.61	.51
Total	.43	.54	.38
n	1728	576	576

The proportions of recalled data are displayed in Table 1, broken down by item type and input serial positions. The single striking effect in the data is the superior recall of incongruent behavior descriptions in comparison to recall of congruent and neutral descriptions, $F(2, 40) = 18.51$, $p < .01$. A multiple comparison test following the Tukey (a) procedure indicated that the incongruent mean recall was reliably higher than the mean proportions recalled from congruent and neutral subsets ($p < .01$), although recall from these latter two subsets did not differ reliably. Twenty-one of the 24 subjects recalled a higher proportion of incongruent behaviors than either of the other two item types. The serial position data show that the superior recall of incongruent behaviors is most pronounced in the middle serial positions of the list and vanishes in the recency portion of the list. A statistical test of the Item Type × Serial Position interaction did not yield a significant result, $F(6, 120) = .98$, *ns,* and so the relationship between recall and serial position has not been clearly established.

The pattern of recall did not vary systematically from the first half of the experimental session to the second. However, the low intrusion rate (recall of nonpresented behaviors), less than one item per trial, did increase slightly over the course of the session. A separate analysis on the order of recall of the three item types to determine whether congruent items were more likely to precede or

follow incongruent items did not suggest that congruent, incongruent, or neutral behaviors were systematically ordered at recall.

An index of recall clustering by item type (congruent, neutral, incongruent) was calculated for each recall protocol (observed stimulus category repetition − expected stimulus category repetition; Bousfield & Bousfield, 1966). An analysis of variance performed on these data revealed no tendency to order recall of behaviors according to the item type (the grand mean of the clustering index was not significantly different from zero, $F(1, 20) = .82$, *ns*.

Discussion

The results of this experiment are evidence for the importance of personality traits as organizing principles in memory for facts about people. Recall of particular behavior descriptions is clearly affected by their relation (congruent, incongruent, neutral) to the salient trait. It is surprising that the incongruent behaviors are so well recalled. Simple versions of schema theories (Bartlett, 1932; Bransford & Franks, 1972; Mandler & Johnson, 1977), organization theories (Bower, 1970; Tulving, 1968), and prototype theories (Cantor & Mischel, 1977; Rosch, 1973) would seem to predict that fitting, congruent, or consistent information would be better recalled than incongruent information. Furthermore, some of these theories would predict that related facts would be recalled together. The failure to observe clustering by trait categories disconfirms this prediction as well.

The present results are related to two phenomena observed in verbal learning research with more traditional list materials. First, it may be that the differential recall of congruent and incongruent behaviors is best viewed as a case of the familiar list-length effect in free recall: As list length increases, the proportion of items recalled decreases (Murdock, 1962). Since there are more congruent behaviors than incongruent ones, proportional recall of congruent items is lower. One problem with this account is the low recall of neutral items that occur with the same frequency as the well-remembered incongruent items. However, it may be that subjects notice incongruent items and class them apart from congruent and neutral behaviors without distinguishing between the latter two types of items. Second, the pattern of recall for the incongruent items resembled the recall of striking "von Restorff" items in certain respects—for instance, the apparent primacy effect in the serial position curve for the incongruent items from early serial positions (Bellezza & Cheney, 1973).

It is important to note that these verbal learning interpretations of the recall results assume that congruent and incongruent items are perceived and mentally categorized by the abstract trait impression and its relation to the individual behaviors. Thus, set size and von Restorff interpretations imply that personality-trait impressions are organizing principles controlling memory for the behavioral information.

Experiment 2

A second experiment was designed to explore the degree to which set size determined the recall of congruent and incongruent behaviors in Experiment 1. Experiments 2 and 3 included conditions in which lists were comprised of equal numbers of congruent and incongruent behavior descriptions. The "pure" effect of the initial trait ensemble on memory, unconfounded with set-size effects, could be assessed under these conditions. These experiments employed the same populations of subjects, task, and materials as Experiment 1, but this time the relative sizes of the congruent and incongruent behavior subsets within each list were varied.

Method

Design. Each subject studied and recalled sentences from eight 16-sentence lists. Each list was associated with personality trait and included four neutral behavior descriptions with varying numbers of congruent and incongruent behaviors. There were four types of lists containing (a) 12 congruent items and no incongruent items; (b) 11 congruent and 1 incongruent items; (c) 9 congruent and 3 incongruent items; and (d) 6 congruent and 6 incongruent items. Each subject studied two lists of each type. Precautions were taken to counterbalance the materials against serial position and list-sequence effects as in Experiment 1.

Materials. The materials from Experiment 1, with the addition of two trait pairs (*generous–stingy* and *calm–nervous*) were used in this experiment. Once again, each list was preceded by an ensemble of eight traits to establish an initial personality impression.

Subjects. The subjects were 24 undergraduate university students paid $1.50 each to participate in the 30-minute experimental session.

Procedure. Instructions and procedures were the same as in Experiment 1.

Results

The primary data from Experiment 2 are the proportions of behavior descriptions recalled. These data are displayed in Table 2 classified according to list type (12/4/0, 11/4/1, 9/4/3, and 6/4/6 congruent/neutral/incongruent behavior subset sizes) and item type (congruent, neutral, and incongruent behaviors). An analysis of variance of the data from the three list types in which all three types of items were presented revealed a large main effect of item type on the proportion of items recalled, $F(2, 36) = 21.43$, $p < .001$. It is clear from these results that the superior recall of incongruent items was almost completely determined by subset size. The fewer incongruent items in a list, the higher the probability of recalling any particular item. An analysis of variance of the proportion-of-incongruent-items-recalled data yielded a significant linear trend across levels of the set-size factor, $F(1, 18) = 10.21$, $p < .01$. The probability of recalling congruent or neutral behaviors did not depend on set size: $F(3, 54) = 2.24$, *ns*, for congruent recall; $F(3, 54) = 1.09$, *ns*, for neutral item recall. Serial position curves were extremely unstable and will not be described for this experiment.

Again, as in Experiment 1, the Bousfield and Bousfield (1966) clustering index was not reliably greater than zero, $F(1, 18) = .79$, *ns*, indicating that subjects were not grouping items by trait categories in recall.

Experiment 3

A third experiment using a new sample of behaviors and four new traits was designed as a systematic replication of Experiment 2. Furthermore, the experiment was designed to obtain stable serial position curves.

Method

Design. Each subject studied and recalled sentences from four 14-sentence lists. Each list was associated with a personality trait and included a mixture of congruent and incongruent behaviors. There were four types of lists containing (a) 13 congruent items and 1 incongruent item; (b) 11 congruent and 3 incongruent items; (c) 9 congruent and 5 incongruent items; and (d) 7 congruent and 7 incongruent items. Each subject studied one list of each type. Precautions were taken to counterbalance the materials against serial position and sequence effects.

Materials. Sentences describing behaviors characteristic of four personality traits were generated by pretest subjects, as in Experiment 1. The four traits, *intelligent, stupid, friendly,* and *hostile,* were selected to span Rosenberg and Sedlak's (1972a) trait space representing poles of their social and intellectual dimensions. A separate sample of 48 subjects rated each of the behavior descriptions on intelligence, friendliness, and imageability scales.

During the memory experiment, each list was preceded by an ensemble of five trait adjectives selected to be close to the key trait in meaning (for example,

7 congruent/ 7 incongruent	.61	336	.67	336

intelligent, knowledgeable, reliable, skillful, persistent, and *scientific*).

Subjects. The subjects were 48 undergraduate university students. They were paid a wage of $2 each to participate in the 1-hour experimental session.

Procedure. The experimental sessions followed the procedure used in the preceding experiments. Subjects studied trait and behavioral information about a character, recalled the behaviors, and then rated their impression of the character. These tasks were repeated for each of four characters.

Results

The pattern of recall data replicated the results of Experiment 2 in almost every detail. These data are displayed in Table 3 classified according to list type (13/1, 11/3, 9/5, 7/7 congruent/incongruent behavior subset sizes) and item type (congruent or incongruent behavior).

Again, a large set-size effect appeared for the recall of incongruent items, such that the larger the set, the less likely that an item was recalled, linear trend $F(1, 47) = 3.80$, $p < .05$. No such effect was apparent in the congruent-item recall data, main effect $F(3, 141) = .35$, *ns*.

A further breakdown of these data yielded the serial position curves displayed in Figure 1. These curves show that the recall advantage of incongruent items over congruent items is most apparent in the central serial positions of the list. Further, when several incongruent items appear, the earliest presented incongruent items have the greatest advantage.

The design of Experiment 3 did not allow a direct analysis of variance test of the reliability of the Serial Position × Item Type × Set Size interaction that is implied by this summary of the serial position data. Twelve pseudosubject units were created by aggregating data from subsets of 4 subjects (in the original sample of 48) to permit an analysis of variance test. For each pseudosubject, the serial position data were combined to yield four Probability of Recall × Serial Position indexes (the first data from true Serial Positions 1 to 3, the second from Positions 4 to 7, the third from Positions 8 to 11, and the fourth from Positions 12 to 14). Thus, an analysis was performed *as if* 12 subjects had each provided data from recall of four serial position locations from four lists (each with a different mixture of congruent and incongruent set sizes). This analysis yielded a significant main effect of serial position on recall, $F(3, 33) = 6.83$, $p < .001$; a significant Item Type × Serial Position effect, $F(3, 33) = 3.04$, $p < .05$; and a significant Item Type × Serial Position × Set Size interaction, $F(9, 99) = 2.70$, $p < .01$—all consistent with our summary of the serial position results.

Again, an analysis of the Bousfield and Bousfield (1966) clustering index produced no evidence of grouping behaviors by trait category in recall, $F(1, 47) = 1.02$, *ns*.

A test of the "pure" trait ensemble effects on recall was performed to answer the question: When congruent and incongruent set sizes are equal, is incongruent-item recall reliably greater than congruent-item recall? An analysis of variance was performed on the proportion of recalled data from equal set-size lists in Experiments 2 and 3 (6 vs. 6 lists in Experiments 2 and 7 vs. 7 lists in Experiment 3). The item (congruent vs. incongruent) effect is significant, indicating that although the absolute difference is small (.09 in Experiment 2 and .06 in Experiment 3) incongruent behaviors are recalled at a higher rate then congruent behaviors, $F(1, 66) = 6.14$, $p < .01$. In Experiment 2, 5 sub-

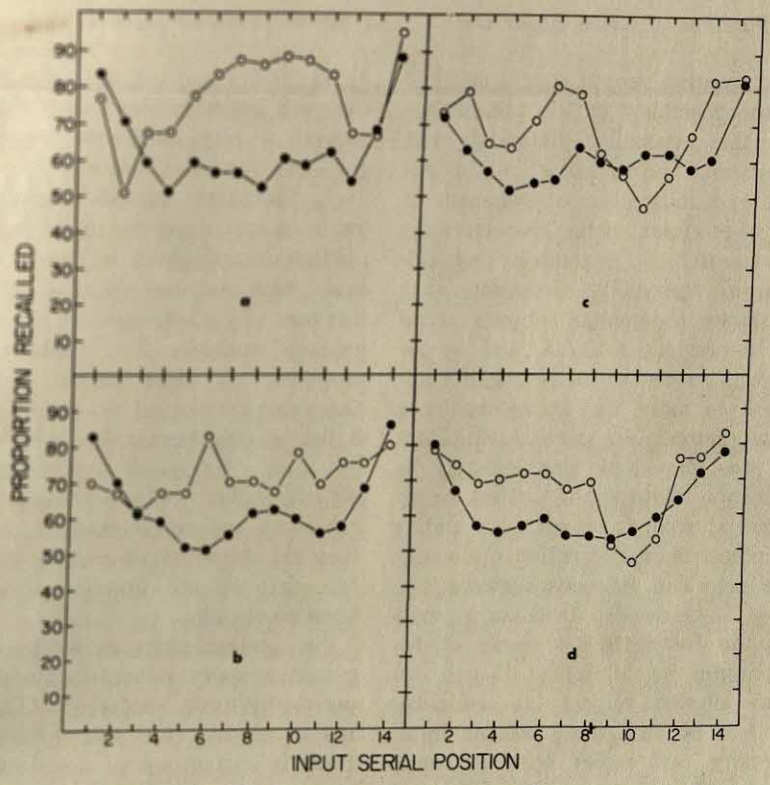

Figure 1. Serial position curves for Experiment 3. (Congruent behavior recall is indicated by filled circles, incongruent behavior recall by unfilled circles. The panels present data from the four set-size conditions in the experiment: [a] 13 congruent items and 1 incongruent item; [b] 11 congruent items and 3 incongruent items; [c] 9 congruent items and 5 incongruent items; [d] 7 congruent items and 7 incongruent items.)

jects recalled equal numbers of congruent and incongruent items, 5 recalled more congruent than incongruent items, and 14 recalled more incongruent items than congruent ones. In Experiment 3, 8 subjects recalled equal numbers, 11 recalled more congruent items, and 29 recalled more incongruent items.

General Discussion

The research reported in this article has established four results about the recall of information about people. First, specific acts that are unexpected or incongruent with reference to a person's general impression are well remembered compared to acts that are unsurprising or congruent. Neutral acts that are uninformative for the impression-judgment task are least well recalled. Second, the primary determinant of the differential recall of congruent and incongruent acts is the relative number of each type of act performed by the person. When the person performs only a few incongruent acts, the relative recall of incongruent items is quite high. When the person performs equal numbers of congruent and incongruent acts, the relative recall advantage of incongruent acts is much smaller. Third, differential recall of congruent and incongruent acts is most pronounced in the central portions of the serial position sequence. Both types of acts are well recalled from early (primacy) and final (recency) serial positions. Fourth, there was no grouping of items in recall by trait categories. Clustering measures revealed no tendency to recall congruent and incongruent acts grouped in any orderly pattern.

Conflicting Findings of Other Studies

We should mention several conditions that may limit the generality of the present results. First, the personality dimension that defines congruence–incongruence in the experimenter's eyes must also be prominent in the subject's perception of the characters. In the present research, we guaranteed this condition by using personality dimensions that have been shown to dominate subjects' social judgments in previous research, and we required subjects to perform a personality-impression task to make the dimensions even more salient. Second, the pace at which information was presented was leisurely in the experiments, allowing the subject to reflect for several seconds on each act and to distribute rehearsal and attention optionally. Third, the retention intervals between presentation of to-be-recalled behavior descriptions and the free-recall test were brief—under 5 minutes for all items. Fourth, the instructions allowed subjects to anticipate the recall tests so that recall was an intentional memory test rather than an unexpected, incidental memory test. Fifth, all memory tests followed free-recall procedures. It may be that the present results would not generalize to cued recalled or recognition test conditions (cf. Cantor & Mischel, 1977).

Several experiments (Bear & Hodun, 1975; Cantor & Mischel, 1977; Greenwald & Sakumura, 1967; Picek, Sherman, & Shiffrin, 1975; Snyder & Uranowitz, 1978; Zadny & Gerard, 1974) have found that information that is consistent with an impression or expectation is better remembered than inconsistent information. Each of these experiments differs from the present research on one or more of the conditions we have listed. Furthermore, several experiments have found that novel (Greenwald & Sakumura, 1967), distinctive (Hamilton & Gifford, 1976), or schema-incongruent (Smith, 1973) information is well remembered. The obvious path for future researchers is to identify the variables that interact with degree of consistency or congruence to produce one pattern of results or another.

A Simple Network Model

Our first cognitive account for these results will begin by describing the interaction between a very long-term conceptual memory store for social information and a relatively short-term episodic memory structure for facts about specific individuals. This distinction is analogous to the distinction between semantic and episodic memory stores proposed by Tulving (1972). Conceptual memory controls the "pattern recognition processes" of identification, comprehension, and categorization of on-going behavior, and it has usually been called implicit personality theory by social psychologists (Rosenberg & Sedlak, 1972a; Schneider, 1973). As behaviors are perceived and comprehended, they are stored in an episodic memory structure that we will describe as a network of associative links.

For present purposes we hypothesize that person memory structures are dominated by personality-trait categories. There are two major reasons for this assumption. First, there is a tradition of describing conceptual person memory, implicit personality theory, as a multidimensional space of trait concepts. Second, the behaviors used as stimulus materials in these experiments were generated by pretest subjects given trait terms as cues. It is difficult to conceive of an alternative standard to the principle of trait congruence that could account for subjects' reliable differential treatment of congruent and incongruent behaviors. It is possible that "behavioral scripts" or schematic images (Schank & Abelson, 1977) are more accurate representations of social categories than trait concepts. However, trait categories seem most appropriate in the present research.

The first analysis of episodic person memory is a network model after the fashion of John Anderson's human associative memory (HAM) theory (Anderson, 1976; Anderson & Bower, 1973; Anderson & Hastie, 1974). This application of HAM is brief, but it would be easy to elaborate the model following the conventions outlined in Anderson's work. First, we suppose that the subject

studying the list of facts about one of our characters produces a mental structure in episodic memory best described as a network of associative *links* and idea *nodes*. We hypothesize that a typical structure encoded in our experimental task has a hierarchical structure of the form depicted in Figure 2. At the highest (entry point) level in the structure are features or ideas such as the individual's proper name, definite descriptions ("the best lawyer in town"), or perhaps a representation of the individual's physical appearance. At the second, intermediate, level of the structure are organizing principles—trait labels in the present experiments. Finally, at the lowest level in the structure are specific facts or attributes of the individual—behavior descriptions in this research. (The HAM analysis actually provides for a much finer-grained analysis of this structure.) Thus, we hypothesize that behaviors are classified into trait categories and stored accordingly during the study phase of our experiments. These assumptions are plausible if we keep in mind that the experimental materials were generated such that each behavior was distinctly and uniquely associated with a single trait category, that incongruent acts were strikingly opposed to congruent acts, and that list presentation was at a leisurely pace so that subjects had time to review each act carefully.

Second, we suppose that during the retention interval, a matter of seconds or minutes in these experiments, links slowly disintegrate or fade from memory.

Third, we postulate a variety of processing rules that operate on the stored memory structure when the signal to recall facts about an individual is given. (a) A search process starts at the highest (proper name) node in the structure and traverses the associative links downwards until it reaches a terminal, behavior description, node. (b) Upon reaching a behavior description, the subject reviews it, to see if that item has been recalled previously, and writes the description on the response form. In our example (Figure 2), the search process would start at the node labeled "James Bartlett," might take the left-hand, "honest trait" path, and then select the path terminating in the behavior description "admitted he caused the accident." (c) If the act has already been recalled, the subject does not write it down. (d) After a behavior has been reviewed, the search process starts over, *from the highest* (entry point) *node*. (e) The probability that the search process chooses a particular link as it passes through a node is determined by

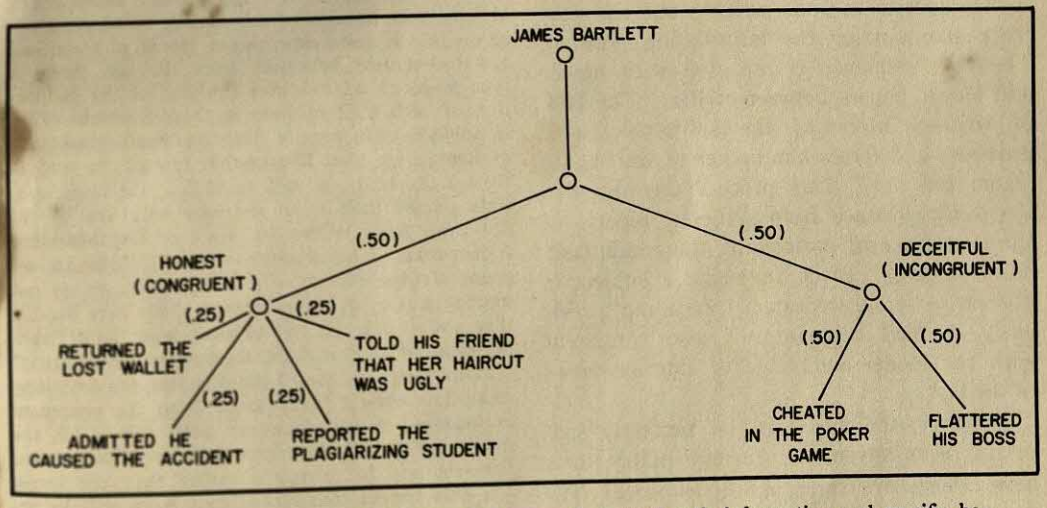

Figure 2. A hierarchical network structure to represent abstract trait information and specific behaviors in long-term memory. (Numbers in parentheses are probabilities of choosing a particular path.)

the number of other links emanating from the node. The probability of choosing a particular path is simply the reciprocal of the number of "departing" links. These traversal probabilities are indicated by the numbers in parentheses in the example in Figure 2. (f) The subject cycles through this retrieval routine for a fixed number of trials. (Twelve to 14 cycles provide the best fits to data from the present research.)

There are several features of this model that may seem implausible to some readers.[1] First, the model will seem too simple, since it relies on a single, orderly mnemonic structure and a small set of processing rules. Of course, the model is not nearly as simple as it appears in this rendering. We urge the interested reader to review the elaborate development in Anderson's (1976; Anderson & Bower, 1973) lengthy theoretical treatises. For the reader who is still dissatisfied, we would argue that the model is complex enough to account for the major features of the data we have presented thus far. Second, the blind, probabilistic search process embodied in the retrieval rules may not appear "intelligent" enough to some readers. It is important to note the pattern of overt behavior that characterizes the recall phase of these experiments. The subject sits quietly for a few seconds, presumably scanning his or her memory for relevant information, and then spends several seconds writing out the sentence summarizing the information recalled. Then the sequence is repeated with longer and longer pauses between writing. The task of writing interrupts the subject's search processes and forces him or her to start again "from the top." This process accords with the weak evidence from subjects' reports of the experience of performing the recall task. The "clogging" effect, in which a subject is unable to avoid repeatedly recalling previously recalled behaviors, is also consistent with the model and subjects' interior views of the task.

However, the model is not perfectly successful even given the current paltry data base. There are three subtle empirical failures. First, the model predicts a set-size effect for congruent-item recall as well as for incongruent-item recall. There is no consistent congruent set-size effect across the three experiments, nor is there a significant effect within any experiment. Second, the model predicts equal recall of congruent and incongruent items when set sizes are equal. Experiments 1 and 2 showed a small, but reliable, recall advantage for incongruent items in equal set-size lists. Third, the simple network model outlined here predicts that incongruent items will tend to be recalled before congruent items in any single output sequence.[2] An analysis of recall output sequences revealed no consistent output priority for incongruent items in any of the three experiments. Thus, we are not overwhelmingly in favor of the simple network model. Its major theoretical function is to show us just how far we can go toward a complete theoretical analysis if we restrict ourselves to very simple associative encoding and retrieval rules and use set size as the primary explanatory construct.

A Depth-of-Processing Model

An alternative account for our experimental results can be developed from Craik and

---

[1] A preliminary remark is necessary about recall of behaviors from the final recency serial positions of the lists in these experiments. Recall of congruent and incongruent behaviors from the last three or four positions was a direct function of the proportion of each kind of item in these positions. That is, subjects were equally likely to recall either type of item, given that it appeared toward the end of the list. Typically, in 90% to 95% of the cases, subjects started their recall sequence with one of the last three items in the list. Both of the theoretical frameworks to be presented below include an account of these recency effects. However, we do not develop arguments about recency effects here because they are not relevant to our analysis of the *differential* recall of congruent and incongruent behaviors.

[2] Obviously, the model predicts that the first item recalled is equally likely to be from the congruent or incongruent sets. However, after this recall, the smaller set, usually incongruent items in the present research, will be exhausted earlier than the larger set. This implies that incongruent items will be recalled earlier than congruent ones. Of course, if set sizes are equal, there would be no differential priority in the output sequence.

Lockhart's (Craik & Lockhart, 1972; Lockhart, Craik, & Jacoby, 1976) levels-of-processing framework.[3] First, certain events in the series of acts are perceptually striking or distinctive. We assume that perceptual distinctiveness is determined by the degree to which an act is congruent with the general impression of a person at the time when the act occurs (Cantor & Mischel, 1977, make a similar proposal in their discussion of recognition memory for traits). Another expression for this characteristic of an event is its *informativeness*. Informative events are "novel," unexpected, or nonredundant with previous information about a person. Crudely speaking, events early in the consequence of acts are more informative than later events; events that disconfirm the current impression of a person are more informative than events that confirm that impression; and events that are extremely inconsistent or incongruent with a prevailing impression are more informative than events that are consistent or only slightly incongruent with that impression. Of course, this list is merely a summary of variables that have been demonstrated to have large effects on the meanings of items in an initial impression (Asch, 1946; Luchins, 1957) or to determine the weights assigned items in information integration tasks (Anderson, 1974b).

Second, distinctiveness or informativeness determines the depth to which an item is processed. The more distinctive or informative an item, the deeper its processing. In the present experimental task, two types of deep processing are particularly important: impression change and causal attribution. We hypothesize that the adjustment of an individual's impression involves special processing of the specific information that leads to that adjustment. We also hypothesize that the subject is very likely to generate causal explanations for distinctive acts. This attribution processing produces deep, durable memory traces in Craik and Lockhart's terms.

Third, deeply encoded acts are less likely than shallowly encoded acts to undergo interference or decay during the retention interval. Finally, deeply encoded acts are retrieved more easily than other acts during the recall phase of the task. Figure 3 summarizes this analysis for the present experimental task. It is clear that this approach can account for the congruence, set size, and serial position results. Again, the primacy results require a further comment. We assume that any initial items are informative and processed deeply. This means that initial congruent items will be well recalled relative to congruent items from the central portions of the sequence, as was observed.

The Craik and Lockhart account, with its emphasis on encoding or perceptual effects, is in the spirit of current models for impression formation and attribution (Ajzen & Fishbein, 1975; Anderson, 1974a; Jones et al., 1972; Kelley, 1973). Furthermore, the Craik and Lockhart approach suggests some additional data analysis. For example, degree of incongruence should be positively related to probability of recall. If we compute correlations between probability of recall and rated extremity of the behavior on the trait dimension relevant to each list across incongruent behavior items, we consistently obtain positive coefficients, although they are not impressively large (Experiment 1, mean $r = .15$; Experiment 2, mean $r = .21$; Experiment 3, mean $r = .07$; none of these values is significantly different from zero).

We should point out that a hybrid model including components of both network and

---

[3] Recently the conceptual analysis underlying the levels-of-processing framework has been challenged (Baddeley, 1978; Nelson, 1977). We retain the levels-of-processing analysis for two reasons. First, acknowledging that the critics have pointed out aspects of the approach that need further conceptual development, that require additional empirical investigation, or that may be incorrect, we still believe that the framework is a useful theoretical analysis. Additionally, we believe that future work on the framework will address all of the critics' objections and yield a more precise and more powerful theoretical structure. Second, everyone agrees that variations in subjects' encoding behaviors are critical determinants of later recall test performance. The Craik and Lockhart framework is the richest current account for variations in processing *quality* as well as *quantity*. Our speculation is that there are differences in the quality of processing afforded incongruent items as compared to congruent items. However, we admit that the present experiments do not provide convincing support for this inference.

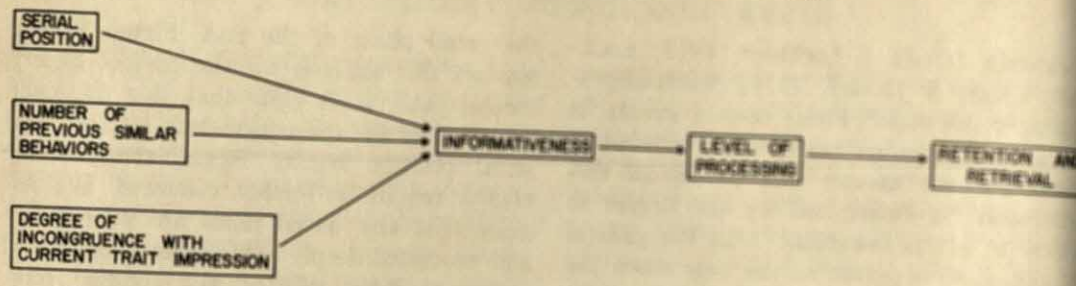

Figure 3. A schematic representation of the variables involved in a depth-of-processing model for the person memory task.

levels-of-processing formulations is easy to imagine. Our preference would be to follow the levels-of-processing analysis of perception and encoding, proposing that deep encoding involves the establishment of more interbehavior links than shallow encoding. Thus, an informative, incongruent act will be linked to more other behaviors than a relatively uninformative congruent act. For instance, we would suppose that causal attribution involves the establishment of a rich network of interitem links between the to-be-explained act and other information about the actor. Retrieval would follow the network model rules of tracing paths through the memory structure and reading out information when new nodes are reached.

Schema Models

A third theoretical account for the present results may be available based on the notion of a schema, frame, or script (Bartlett, 1932; Bobrow & Norman, 1975, Neisser, 1976; Minsky, 1975; Schank & Abelson, 1977). Such an explanation would postulate a mental representation with a central "principle," "terminal slot," or "stereotyped action sequence." Early information (for instance, the trait ensemble in our experiments) would activate or select such a data structure. For the moment, we think that our results present a challenge to schema theorists, because no particular current schema theory appears to provide an account for the pattern of data obtained in these experiments. Of course, we do not doubt that a schema theory can be developed to account for the results of the present research. In fact, Winston (1977) points out that schema models are more powerful than the network models we have outlined. But, at present, no such explicit schema memory model is in the literature.

Conclusion

The present research establishes the significance of abstract trait information in determining the recall of specific behaviors. The effects of congruence or consistency among acts attributed to a person depend on the primacy of the trait impression in perception and memory. There is no way to explain the large, reliable congruence and set-size effects obtained in this research without reference to a standard of consistency such as the abstract trait impression. For the present, it remains to be seen whether a network model, a depth-of-processing model, or some currently unspecified alternative will provide the most satisfactory account of these results. We are also curious as to what extent the neat pattern of results obtained in our laboratory task will generalize to people and settings in the real world.

Notice on Author Alterations

Effective January 1979, the procedure for billing authors for alterations will change. Authors of articles in APA journals are customarily charged for alterations on proofs that result from (a) authors' errors or omissions in the manuscript and (b) changes that result from authors' failure to review the edited manuscript or the proof. Until now, alteration charges have been determined by the number of lines affected by changes requested and have been based on 1974 printing rates. Beginning with the proofs for the first issues of 1979, authors' alterations will be determined not only by the number of lines affected but also by the number of figures and pages affected and will be based on current printers' rates.

This change in alteration billing is being made so that alteration charges will more closely reflect the actual cost of changes requested and may mean larger alteration bills for some authors. Authors are reminded that alteration charges apply only when changes are made on proofs and that *there is no charge* for changes made at the manuscript stage.

Based on Wortman and Brehm's integration of reactance theory with Seligman's model of learned helplessness, an investigation was conducted to examine the effects of amount of helplessness training and internal–external locus of control on subsequent task performance and on self-ratings of mood. Subjects were divided into "internal" and "external" groups and were then given either high, low, or no helplessness training on a series of concept-formation problems. After completing a mood checklist, all subjects worked on an anagram task presented as a second experiment by a second experimenter. The results revealed that internals exhibited greater performance decrements and reported greater depression under high helplessness than did externals. In the low helplessness conditions, internals tended to perform better than control subjects, while externals tended to perform worse than control subjects; low helplessness subjects also reported the highest levels of hostility. The results are discussed within the context of Wortman and Brehm's integration of reactance and learned helplessness theories.

Seligman (1972, 1975) has proposed that learned helplessness, a phenomenon originally demonstrated in animal research, may underlie human reactive depression. According to learned helplessness theory, when individuals are exposed to situations in which reinforcements are independent of responses, they gradually develop the expectation that reinforcements cannot be controlled. This expectation of uncontrollability reduces the person's motivation to respond in new situations, interfering with performance on new tasks, and leads to anxiety and a state of depression, because of the perceived lack of control over outcomes.

This article is based on a master's thesis submitted by the first author to the Graduate College of the University of Maryland. The authors thank Mary Faith Tanney, Barry Smith, and Clara Hill, who served on the examining committee, and Susan Adams, who served as the second experimenter.

Wortman and Brehm (1975) have proposed an integration of the learned helplessness model with reactance theory. According to reactance theory, individuals who expect to have control (i.e., freedom to obtain an outcome) are motivationally aroused to restore control when it is threatened or reduced. This motivational arousal may be accompanied by hostility and aggression. In integrating the two theories, Wortman and Brehm suggested that mild experiences with helplessness training will result in reactance and improved performance on subsequent tasks in an effort to reassert control, while more extensive experience with uncontrollability will lead to passivity and debilitated performance on new tasks. Several investigators have reported evidence consistent with this hypothesized relationship between amount of helplessness training and subsequent task performance (e.g., Roth & Bootzin, 1974; Roth & Kubal, 1975).

Learned Helplessness and Mood

There is a substantial amount of evidence consistent with the hypothesis that experience

Copyright 1979 by the American Psychological Association, Inc. 0022-3514/79/3701-0039$00.75

with uncontrollable contingencies leads to depression. Miller and Seligman (1973) found that depressives were more likely than nondepressives to view reinforcements as independent from responses. Klein, Fencil-Morse, and Seligman (1976) found that nondepressed subjects given helplessness training on a series of unsolvable problems exhibited impaired performance on a subsequent task and that this impaired performance was similar to the performance of depressed subjects not given helplessness training. Both Gatchel, Paulus, and Maples (1975) and Miller and Seligman (1975) found that subjects subjected to inescapable aversive noise exhibited increases in levels of reported depression, anxiety, and hostility on the Multiple Affect Adjective Checklist compared to their pretest responses. Griffith (1977), using a forced-choice mood scale that paired depression and anxiety adjectives in order to assess the relative balance of depression and anxiety, gave helplessness subjects 10 trials of noncontingent feedback on each of four concept-formation problems. Half of these subjects were also told that they had failed on each problem; the other half were told that they had succeeded on each problem. Results on the mood checklist indicated that noncontingent feedback – failure subjects changed in the direction of increasing depression after treatment, while subjects in the noncontingent feedback – success group changed in the direction of increasing anxiety. Both groups exhibited performance decrements on a posthelplessness solvable anagram task. Finally, Glass and Singer (1972) obtained self-ratings in one investigation that revealed that subjects who perceived no control over an aversive stimulus rated themselves as significantly more helpless, incompetent, and weak than subjects who perceived control over the same stimulus.

While there is considerable support for a relationship between helplessness training and depression, the question of whether different moods are experienced by subjects after different amounts of helplessness training has received less attention.[1] One major purpose of the present study was to assess whether, as Wortman and Brehm (1975) imply, subjects initially respond to uncontrollab by experiencing frustration and/or host but become resigned and depressed as controllability continues.

Learned Helplessness and Locus of Contr

The second major purpose of the pres study was to examine the relationships tween locus of control, amount of helple ness training, and subsequent mood and ta performance. The personality dimension Internal–External (I–E) Locus of Cont (Rotter, 1966) refers to the extent to whi an individual generally perceives reinforc ments as response dependent or controllabl Internal individuals tend to perceive rei forcements to be response dependent, whi external individuals tend to perceive rei forcements as response independent. Give Wortman and Brehm's (1975) suggestion that initial expectations of control affect re sponses to uncontrollability, it might be ex pected that internals and externals would react differently to helplessness training.

Individuals who expect control should be more likely to experience reactance when confronted with uncontrollability than individuals who do not expect control. If internals have greater expectations of control than externals, then internals should also exhibit more pronounced reactance effects when given mild experiences with uncontrollability. It might also be suggested that individuals who expect control will be affected more severely by helplessness training once they realize that they truly have no control. Watson and Baumel (1967) and Petzel and Gynther (1970) have suggested that internals are more uncomfortable with uncontrollability than externals, because of the incongruence between their expectations of controllability and the uncontrollable situation. These predictions were examined in the present

[1] In the important conditions of their study, Roth and Kubal (1975) found general increases in depression, anger, and anxiety as helplessness training increased. Several procedural differences between the Roth and Kubal study and the present investigation are discussed in the final section of this article.

study by exposing groups of internals and externals to one of several levels of helplessness training.

Method

Design

The design was a 2 × 3 between-groups factorial, with three levels of helplessness training on a concept formation task (high helplessness, low helplessness, and no-helplessness control) crossed with two groups of subjects selected on the basis of their extreme internal or external scores on the I–E scale (Rotter, 1966). The proportion of noncontingent incorrect feedback on the concept formation problems was held constant at .5 for all low and high helplessness subjects. A yoked contingent and noncontingent feedback design was not employed, since practice effects could be expected to lead to differential overall proportions of correct and incorrect feedback as a function of the number of problems in the contingent feedback conditions.[2] A review of previous studies that employed similar concept-formation tasks and both contingent feedback (nonyoked) and no-feedback control groups (e.g., Benson & Kennelly, 1976; Griffith, 1977; Hanusa & Schulz, 1977; Hiroto & Seligman, 1975; Klein et al., 1976; Roth & Kubal, 1975; Tenner & Eller, 1977) indicated that contingent feedback either enhanced performance or did not affect performance compared to no-feedback or baseline subjects. A no-feedback procedure was therefore employed in the no-helplessness control conditions of the present study.

Subjects

Ninety students were selected on the basis of their scores on the Rotter I–E scale. Three hundred eighty-five students in introductory psychology were given the I–E scale by their discussion leaders. Subjects with scores above 15 and below 8 on the I–E scale were assigned to the external and internal groups, respectively, and were called and asked to participate in two different learning experiments. The 90 subjects were randomly assigned to one of the three conditions within levels of externality. Each subject was run individually and received two credits for participation in the experiment.

Procedure

A series of five-dimensional stimulus patterns previously used in discrimination learning studies (Levine, 1966) and in other helplessness studies (cf. Hiroto & Seligman, 1975; Klein et al., 1976) were used for the treatment task. Each of the five dimensions had two values: (a) letter (A or T); (b) letter color (black or red); (c) letter size (upper- or lowercase); (d) border surrounding letter (circle or square); and (e) underline (dotted or solid). Two stimulus patterns were shown on each 3 × 5 card. One pattern consisted of a set of values from each of the five dimensions; the other pattern consisted of the complimentary values of the dimensions.

All subjects were given six concept identification problems by the first experimenter, who was seated next to the subject at a table (the first experimenter was unaware of the subject's I–E scale score). Subjects in the helplessness groups were told that for each card, the task was to choose which side of the card contained the "correct" value, arbitrarily set by the experimenter, and that from the experimenter's feedback ("correct" or "incorrect") they should learn the correct answer and choose correctly as often as possible. Subjects in the low helplessness groups were told that for several problems they would be asked to work without feedback, to provide a "baseline." Subjects in the control groups received the same task description as those in the helplessness groups, but were told that the experimenter needed a baseline of choices made without feedback for all of the problems.

All subjects initially received one 10-trial sample problem to clarify the tasks. After the sample problem, all subjects were told that it was very important for the experiment that they work hard, and if they did their best on the task in the experimenter's judgment, they would receive an additional credit. These instructions were given to motivate subjects to attend to the tasks and to try harder. Subjects then received six problems, 10 trials per problem.

High helplessness. Following the sample problem and offer of credit incentive, predetermined noncontingent feedback (example: CICICCICI) was given for each problem; incorrect feedback was always given on the last trial. After each set of 10 trials, subjects were asked to state what they believed was the "correct" value for that set but were given no feedback concerning their answer.[3] They were then told to start the next problem, whose

---

[2] Since the training conditions differed in the absolute amount of feedback, it might be argued that the sheer amount of negative feedback, rather than the noncontingency of feedback, could account for the obtained results. While this interpretation is possible, it is unlikely, since (a) other investigations in which yoked controls were employed have demonstrated helplessness effects (e.g., Glass & Singer, 1972; Hiroto & Seligman, 1975), and (b) noncontingent success has been shown to produce helplessness (Benson & Kennelly, 1976).

[3] Pretesting indicated that subjects became suspicious when they were given incorrect feedback at the end of all six problems, so subjects were simply given no feedback on their final guesses to eliminate suspicion.

value might or might not be the same as that of the previous problem.

Low helplessness. For the first four problems, subjects were asked to choose the correct side and value without any feedback, to provide a baseline for their performance. For the last two problems, contingent feedback was given using the same procedure as in the high helplessness conditions.

Control. Subjects in this condition were asked to guess the correct side for all problems without any feedback, to provide a baseline for guessing for use with other subjects who would receive feedback.

In all conditions, the experimenter recorded all of the subject's responses. No trial was allowed to exceed 15 sec; after 10 sec subjects were told that they had 5 sec left to make their choice.

Mood assessment. The Multiple Affect Adjective Checklist (MAACL) Today Form (Zuckerman & Lubin, 1965) was given to all subjects immediately following the treatments. Subjects were told that their responses would be anonymous and that they were being asked to fill out the checklist because the experimenter wanted to include their current feelings with the results. The MAACL provides measures of three negative affective states: anxiety, depression, and hostility. After reading the standard instructions and completing the MAACL, all subjects received two credits and were thanked for their participation.

Solvable test task. The test task was conducted at a different location by the second experimenter, who was always blind to conditions, immediately following the first experiment. When the subject reported, the second experimenter explained that she was "developing norms for anagram solution times from a cross section of students." The subject's task was to solve a series of anagrams. The experimenter explained that there could be a pattern by which to solve all of the anagrams but that it was up to the subject to figure that out. Subjects were told to give their solution as rapidly as possible, since their performance was being timed. If the subject stated an incorrect solution, the experimenter said, "No, that's not it." If the subject stated the correct word, the experimenter said, "Yes, that's it," recorded the time to solution, and handed the subject the next anagram.

Twenty solvable anagrams were given, each on a 3×5 card. All anagrams had the same letter sequence (e.g., ECUNL–UNCLE) and were obtained from Tresselt and Mayznor (1966). Three measures of anagram performance were obtained: (a) trials to criterion, defined as the solution of three consecutive anagrams in less than 15 sec; (b) number of failures to solve within 100 sec, at which point the trial was ended; and (c) mean response latency for the 20 anagrams.

Following the anagram trials, the first experimenter entered the second experimenter's room, having "forgotten" to give the subject a questionnaire about the first learning experiment. The questionnaire assessed perceptions of task solvability before and after treatment, level of motivation, degree of success on the task, and likelihood that others would be able to solve the concept-formation problems. All subjects were then debriefed by the first experimenter.

Results

I–E Scale Scores

A 2×3 analysis of variance of the I–E scores indicated the expected main effect for the I–E variable, $F(1, 84) = 1,151.44$, $p < .001$, such that subjects in the external conditions had higher scores than subjects in the internal conditions ($M = 18.20$ and 4.20, respectively). Neither the main effect for helplessness nor the two-way interaction was significant, $F(2, 84) = .59$ and 1.16, respectively.

Anagram Performance

A 2×3 analysis of variance of the trials-to-criterion measure indicated a significant main effect for the helplessness variable, $F(2, 84) = 81.97$, $p < .001$, such that subjects in the high helplessness conditions performed worse than subjects in either the low helplessness or the control conditions. The main effect for I–E was not significant. However, the analysis indicated a significant interaction between the helplessness and I–E variables, $F(2, 84) = 14.99$, $p < .001$ (see Table 1). Although internal and external subjects did not differ from each other in the control condition ($F < 1$), they reacted in opposite ways to the low helplessness manipulation. Low helplessness–internal subjects performed significantly better than control–internal subjects, $F(1, 84) = 4.32$, $p < .05$, a reactance effect. Low helplessness–external subjects, however, performed significantly worse than control–external subjects, $F(1, 84) = 5.92$, $p < .05$. In the high helplessness conditions, both internals and externals performed significantly worse than their appropriate controls, $F(1, 84) = 90.41$, $p < .001$, and $F(1, 84) = 40.80$, $p < .001$, respectively; in addition, high helplessness–internal subjects performed significantly worse than high helplessness–external sub-

Table 1
Mean Anagram Performance as a Function of Helplessness Training and Internal–External Classification

Group	High helplessness	Low helplessness	Control
	Trials to criterion		
Internal	16.80	5.66	7.66
External	14.40	10.60	8.26
	No. of failures to solve		
Internal	4.80	.73	1.40
External	3.06	2.13	1.53
	Mean response latency (in sec)		
Internal	51.02	24.84	29.51
External	42.85	37.43	30.93

Note. The number of trials to criterion could range from a minimum of 3 (if the first 3 anagrams were each solved in less than 15 sec) to a maximum of 20 (if criterion was never reached); the number of failures to solve could range from 0 (if every anagram was solved) to 20 (if none of the anagrams were solved); the maximum possible response latency was 100 sec (the point at which a trial was terminated).

jects, $F(1, 84) = 6.23$, $p < .05$. Statistically weaker Helplessness × I–E interactions of similar form were also obtained for the number of failures to solve, $F(2, 84) = 3.75$, $p < .05$, and for mean response latencies, $F(2, 84) = 4.42$, $p < .05$ (see Table 1).

Mood Indexes

Depression. A 2 × 3 analysis of variance of the depression scores from the MAACL yielded a significant main effect for helplessness, $F(2, 84) = 91.86$, $p < .001$, such that subjects in the high helplessness conditions were more depressed than those in the low helplessness and control conditions. The main effect of the I–E variable was also significant, $F(1, 84) = 5.12$, $p < .05$, such that internal subjects reported themselves to be more depressed than external subjects. The interaction between helplessness and I–E was also significant, $F(2, 84) = 6.34$, $p < .01$. While internal and external subjects did not differ from each other in the control and low helplessness conditions (Fs < 1), in the high helplessness condition, internals were significantly more depressed than externals, $F(1, 84) = 17.76$, $p < .001$ (see Table 2).

Hostility. A 2 × 3 analysis of the hostility scores (see Table 2) yielded a significant main effect for helplessness, $F(2, 84) = 43.29$, $p < .001$. There were no other significant effects on this measure. Comparisons of the marginal means indicated that high helplessness subjects were significantly more hostile than controls, $F(1, 84) = 39.07$, $p < .001$ (overall $M = 12.37$ and 6.94, respectively). Low helplessness subjects were significantly more hostile than high helplessness subjects, $F(1, 84) = 8.05$, $p < .01$ (overall $M = 14.83$ and 12.37, respectively).

Anxiety. A 2 × 3 analysis of the anxiety scores (see Table 2) yielded a significant main effect for the I–E variable, $F(1, 84) = 5.32$, $p < .05$, such that internal subjects overall reported more anxiety than external subjects (overall $M = 10.27$ and 9.22, respectively). The main effect for helplessness was also significant, $F(2, 84) = 49.64$, $p < .001$. Since no predictions had been made for anxiety scores, a Newman-Keuls analysis was performed on the marginal means. This analysis indicated that although subjects in the low and high helplessness conditions did not differ, both groups reported significantly greater anxiety than controls ($p < .01$). The

Table 2
Multiple Affect Adjective Checklist Means

Group	High helplessness	Low helplessness	Control
	Depression		
Internal	26.60	12.80	11.93
External	20.86	13.13	12.00
	Hostility		
Internal	12.80	15.73	7.00
External	11.93	13.93	6.87
	Anxiety		
Internal	12.40	11.20	7.20
External	10.80	10.87	6.00

Note. For each mood measure, the higher the score, the greater the mood. Mood scores could range from a minimum of 0 to a maximum of 40 for depression, 28 for hostility, and 21 for anxiety.

interaction on this measure was not significant.

Questionnaire Responses

A 2 × 3 analysis of the question that asked subjects how hard they had worked on the concept-formation task indicated that there were no significant main or interaction effects (all Fs < 1). All groups reported that they had worked hard on the task (on the 7-point scale, where 1 was labeled "extremely hard," the means ranged from 1.93 to 2.47).

The second question dealt with subjects' perceptions of their performance on the concept-formation task. A 2 × 3 analysis of variance of these ratings indicated that there was a significant main effect for helplessness, $F(2, 84) = 51.14$, $p < .001$. There were no significant effects for the I–E variable or for the two-way interaction. Analysis of the marginal means indicated that high helplessness subjects rated themselves as less successful than low helplessness subjects and that the low helplessness subjects rated themselves as less successful than control subjects ($p < .01$, Newman-Keuls).

There were no significant main effects or interactions on the question that assessed whether subjects perceived the concept-formation task to be solvable at the beginning of the task (all Fs < 1), and all groups rated the task as solvable. The fourth question assessed subjects' perceptions of their ability to solve the task after they had worked on it. A 2 × 3 analysis of variance indicated that only the main effect for helplessness was significant on this measure, $F(2, 84) = 24.97$, $p < .001$. A Newman-Keuls analysis of the marginal means indicated that low helplessness subjects believed that they were less able to solve the task than did control subjects ($p < .01$), and high helplessness subjects believed that they were significantly less able to solve the problems than did low helplessness subjects ($p < .01$).

While the fourth question concerned subjects' perception of their own ability to solve the problems, the fifth question asked subjects to what extent they believed that the problems could be solved by someone else. In order to examine the relative decline in belief in one's own and another's ability to solve, a 2 × 2 × 3 analysis of variance with type of question as the repeated factor was performed. In addition to main effects for the type of question and the amount of helplessness training, an interaction between these two variables was obtained, $F(2, 84) = 13.56$, $p < .001$. Control subjects believed that both they and others could solve the problems ($M = 6.30$ for self and 6.23 for others on the 7-point scale), but both low and high helplessness subjects reported that they believed they were less able to solve than others (in low helplessness, $M = 4.13$ for self and 5.67 for others; in high helplessness, $M = 2.70$ for self and 4.43 for others). Although these data should be interpreted with caution, since they were collected at the very end of the experimental sessions, they seem to indicate that subjects in the helplessness conditions were attributing their inability to solve to themselves. High helplessness subjects in particular believed that they could not solve the problems, but tended to believe that others could.

Discussion

Overall Mood Patterns

The mood results were generally consistent with Wortman and Brehm's (1975) prediction that individuals will initially respond to uncontrollability by experiencing reactance but will eventually exhibit helplessness after continued experience with lack of control. In the present study, low helplessness subjects were significantly more hostile than either high helplessness or control subjects, while high helplessness subjects were significantly more depressed than either low helplessness or control subjects. These results are consistent with Wortman and Brehm's model, but they are somewhat discrepant with Roth and Kubal's (1975) finding that increases in helplessness training led to increases in depression *and* anger when the training task was important. There are several possible reasons for this apparent discrepancy. While Roth and Kubal used a

series of 7-point Likert-type scales to measure affect at the end of the second (test) task, in the present investigation moods were measured with the MAACL immediately following the training task. In addition to the possibility that the measuring instruments used in the two studies may have tapped different mood states, subjects' ratings of their moods immediately after helplessness training may differ from their subsequent retrospective reports. Finally, since moderate internals and externals were excluded from the present study but were presumably included in Roth and Kubal's investigation, it is possible that moderates on the I–E scale react differently than their more extreme counterparts.

The mood results also indicated that both high and low helplessness pretreatments produced anxiety, consistent with the findings of Gatchel et al., (1975), Miller and Seligman (1975), and Roth and Kubal (1975). The anxiety data do not, however, provide support for the alternative hypothesis that impaired performance following helplessness training is due to anxiety (Hebb, 1966, as cited in Wortman & Brehm, 1975). High and low helplessness subjects did not differ in reported anxiety but exhibited quite different levels of performance on the anagram test task. Furthermore, anxiety and performance were not significantly correlated (see Table 3).[4]

Locus of Control, Mood, and Performance

For internals, the pattern of performance results was also compatible with Wortman and Brehm's prediction that individuals who initially expect control will attempt to reassert control after mild experiences of uncontrollability but will eventually show helplessness effects when the uncontrollability is extensive. Low helplessness internals exhibited improved performance on the anagram task relative to controls, while high helplessness internals displayed the greatest performance decrements in the experiment. Under low helplessness, internals' hostility was also negatively correlated with failures, such that the more hostile they were, the more anagrams they solved (see Table 3). Under high helplessness, internals' depression, rather than hostility, was most highly correlated with number of failures. For these subjects, the higher their reported depression, the fewer anagrams they solved. That hostility was related to enhanced performance under low helplessness for internals was a finding particularly supportive of Wortman and Brehm's (1975) model.

Table 3
Within-Cell Correlations Between Mood Indexes and Number of Failures to Solve on the Anagram Task

Group	High helplessness	Low helplessness	Control
	Depression vs. no. of failures to solve		
Internal	.74**	.33	.71**
External	.75**	.41	.43
	Hostility vs. no. of failures to solve		
Internal	.14	−.52*	.12
External	−.41	−.43	−.43
	Anxiety vs. no. of failures to solve		
Internal	.39	.34	−.36
External	−.50	.00	−.13

* $p < .05$.
** $p < .01$.

Externals, however, showed a different pattern of performance. As the amount of uncontrollability increased for these subjects, their performance became increasingly worse. This finding is consistent with Wortman and Brehm's notion that individuals who do not initially expect control will not experience reactance and will show helplessness effects after mild experience with uncontrollability. However, externals were unexpectedly similar to internals in their pattern of moods. As would be expected under high helplessness, externals showed substantial depression (although less than internals), and the correla-

[4] Within-cell correlations between the mood indexes and the number of failures to solve are displayed in Table 3. The correlations between moods and the other measures of performance followed a similar pattern but were generally weaker.

tion between externals' depression and number of failures to solve was similar to that of internals (see Table 3). However, under low helplessness, externals were also similar to internals in that they were more hostile than control subjects; but unlike the internals, externals performed worse on the anagram task than controls. Also in contrast to the relationship for internals, the correlation between hostility and failures for externals was unchanged in all three helplessness conditions (see Table 3). Therefore, while mild experience with uncontrollability led externals to become hostile, this treatment did not appear to alter the relationship between hostility and performance.

That both internal and external subjects were hostile after mild experience with uncontrollability could mean that both groups experienced reactance but behaved differently in response to reactance. This interpretation implies that some aspect of the I–E variable other than initial expectations of control may have led to the different behavior patterns that were obtained. For example, internals and externals may differ in their characteristic response to failure to exert effective control, such that internals initially tend to exert more effort whereas externals rapidly give up. This could explain why both internal and external low helplessness subjects expressed hostility, but only internals displayed enhanced anagram task performance. Cohen, Rothbart, and Phillips's (1976) finding that the effects of learned helplessness tend to generalize more easily for externals is also consistent with this interpretation.

Overall, the findings of the present investigation for internals were consistent with Wortman and Brehm's (1975) predicted sequence of both moods and performance following experience with uncontrollability. The performance of externals was also compatible with Wortman and Brehm's model; however, the increased hostility of externals in the low helplessness condition may not be consistent with an expectation interpretation and indicates that it would be useful to determine the actual critical difference between internals and externals that accounts for their different responses to uncontrollability. In the present investigation only total I–E scores from a mas testing were available for analysis; it woul be interesting in future studies to focus o specific factors of the I–E scale. Investigator have found the I–E scale to contain from tw (e.g., Mirels, 1970) to as many as five fac tors (see Phares, 1976, for a review of these studies). Since, as Phares has observed, the ability to derive reliable separate factors from the original scale is limited because of the small number of items (23), it might be useful to employ either an expanded version of the scale or subscales specifically designed to tap expectations of control versus habitual reactions to uncontrollability. The effects of expectations of control on reactions to helplessness training should also be directly studied by employing unambiguous manipulations of expectations instead of individual difference variables.

Correction to Stephan and Rosenfield

In the article, "Effects of Desegregation on Racial Attitudes," by Walter G. Stephan and David Rosenfield (*Journal of Personality and Social Psychology*, Vol. 36, No. 8, pp. 795–804), the following corrections should be made in Table 2 on page 800: (a) The correlation between parental authoritarian child-rearing practices and changes in racial attitudes should be −.04, not .04. (b) The correlation between parental opposition to integration and increases in self-esteem should be .16, not −.16.

Source Credibility in Social Judgment: Bias, Expertise, and the Judge's Point of View

Michael H. Birnbaum and Steven E. Stegner
University of Illinois at Urbana-Champaign

Mathematical models of source credibility were tested in five experiments in which judges estimated the value of hypothetical used cars based on blue book value and/or estimates provided by sources who examined the cars. The sources varied in mechanical expertise and in bias; they were described as friends of the buyer or seller of the car or as neutral. Individuals judged the highest price the buyer should pay, the lowest price the seller should accept, and the "true" value ("fair" price) of the car. Data indicated that expertise amplifies the effect of the source's bias. This effect is predicted by a scale-adjustment model, in which the source's bias shifts the scale value of the source's estimate. The weight of an estimate depends chiefly on the source's expertise. The weight of an estimate also depends configurally on the other estimates: Judges instructed to take the buyer's point of view give greater weight to the lower estimate, whereas judges who identify with the seller place greater weight on the high estimate. Simple premises about human judgment give a good account of the data.

Social judgments often require the combination of pieces of information provided by sources who vary in credibility (Hovland, Janis, & Kelley, 1953; McGuire, 1968). Rosenbaum and Levin (1968, 1969), Anderson (1971), Birnbaum, Wong, and Wong (1976), and Birnbaum (1976) have proposed and/or tested formal theories of source credibility. The present research extends these developments and argues that the concept of *credibility*, used loosely in early persuasion research to mean "believability," can be profitably decomposed into at least three constructs: expertise, bias, and the judge's point of view.

The *judge* is the person (the subject in the present experiments) who combines information provided by one or more *sources* to make an overall evaluation or judgment. The juror, who decides guilt based on contradictory evidence, the voter, who chooses among candidates who disagree, and the consumer, who evaluates the worth of a product, are examples of people acting as judges.

The *expertise* of the source refers to the perceived correlation between the source's report and the outcomes of empirical verification. Expertise would be expected to depend upon such factors as training, experience, and ability. For example, a doctor whose diagnoses are often confirmed in the post mortem would be considered a more expert source of information about the state of a person's health than would an untrained student.

The *bias* of the source refers to factors that are perceived to influence the expected algebraic difference between the source's report and the true state of nature. For example, a Republican might be considered a biased source of information about a Democrat who is running for office.

The distinction between expertise and bias is like the distinction between regression slope and intercept. For example, a used car salesman might be an expert source of information about the value of his cars; however, the salesman's estimates may be biased upward, since the seller stands to profit by convincing potential

This research was supported in part by a grant from the Research Board, University of Illinois. We are grateful to Marcy Wilhite and Michael Less for assistance and to Samuel Komorita, Barbara Mellers, Clairice Veit, and Robert Wyer for helpful comments on the manuscript.

buyers of the high worth of the car. Similarly, an insurance claims adjuster is an expert source who might underestimate the value of damaged goods on which his or her company is required to pay claims.

The judge's bias is termed the judge's "point of view." Thus, a judge who is a Republican or a Democrat may treat information provided by a Republican source and a Democratic source differently. It is important to maintain the distinction between the bias of the sources and the point of view (bias) of the judge who combines the information from the sources.

Previous Research on Source Expertise

Rosenbaum and Levin (1968, 1969) extended an averaging model of impression formation to account for source credibility effects. Anderson (1971) discussed additive and averaging models of source credibility and theorized, on the basis of previous research (on the set-size effect in impression formation), that averaging models would prove superior. Wyer (1974) revived an additive model for source credibility as a "case against averaging." Lichtenstein, Earle, and Slovic (1975) offered a constant-weight averaging model of numerical cue prediction (each cue can be thought of as a source). Additive and averaging models both predict that the effect of a source's report should increase with increased credibility, but the models make different predictions for the effect of the credibility of one source on the effect of information provided by another source.

Birnbaum et al. (1976) and Birnbaum (1976) conducted three experiments testing three models for the effect of source expertise in information integration. In one experiment (Birnbaum et al., 1976, Experiment 1) undergraduates judged the value of used cars based on two cues: blue book value and an estimate provided by one of three sources who examined the car. The three sources differed in mechanical expertise. For example, how much is a car worth if its blue book value is $500 but an expert mechanic who has examined the car evaluates its worth at $700? In the second experiment, judges rated the likableness of hypothetical persons described by personality-trait adjectives attributed to sources who varied in their length of acquaintance with the person they described. For example, how much would you like a person who was described by an acquaintance of 3 years as *sincere* and by an acquaintance of 3 weeks as *phony?* In a third experiment (Birnbaum, 1976), students were trained with feedback to predict a numerical criterion from single independent cues separately, then asked to predict (without feedback) the criterion from pairs of cues.

The results of the used car, impression formation, and numerical prediction studies form a coherent picture. The effect of a cue varies inversely with the number of cues presented, contrary to the additive models. Furthermore, the effect of a cue varies inversely with the credibility of the other cues, in violation of the constant-weight averaging model (including the models of Rosenbaum & Levin, 1968, 1969, and Lichtenstein et al., 1975, as special cases). The results of Birnbaum et al. (1976) and Birnbaum (1976) were qualitatively consistent with a relative-weight averaging model, in which the effect of information provided by one source is inversely related to the number and credibility of the other sources.

Since the results of the three quite different experiments were consistent with the same general model, it is inductively appealing to theorize that the model will hold across different judgmental domains. Values of the estimates, adjective likableness values, and numerical values of the cues are represented by scale values. Levels of mechanical expertise, length of acquaintance, and cue-criterion validity are represented by changes in weight.

The relative-weight averaging model for used car judgment can be written as follows:

$$R = \frac{w_0 s_0 + w_V s_V + w s_E}{w_0 + w_V + w}, \qquad (1)$$

where R is the judged worth; w_0, w_V, and w are the weight of the initial impression, the blue book, and the source, respectively; and s_0, s_V, and s_E are the scale values of the initial impression (the presumed response in the absence of information), the blue book value, and the source's estimate, respectively.

Purposes of the Present Research

The present research investigates the effects of the source's *bias* and the judge's *point of view* on the information integration process. Judges made evaluations of hypothetical used cars based in part on estimates provided by sources who varied in bias and expertise. Bias was manipulated by stating that the source was either a friend of the buyer or the seller or an independent. The judge's point of view was manipulated by asking the judge to identify with either the buyer or the seller of the car. For example, subjects were asked to judge the *most they would advise the buyer to pay* for a car, given that the blue book value is \$500 and an *expert* mechanic, who is a *friend of the seller*, estimates its value at \$700. The bias of a source may affect either the weight or the scale value of the information provided by the source. Furthermore, the effects of the source's bias may depend on the judge's point of view. The next section shows that certain experimental designs make it possible to distinguish different theories of the effect of source characteristics on weight and scale value.

The first four experiments compare three models of the effects of the source's bias. These relative-weight averaging models are compatible with previous research; however, they make strikingly different predictions for the interaction of the source's expertise and bias. The models can be distinguished by qualitative comparisons that do not require metric assumptions about the dependent variable or global tests of goodness of fit.

The fifth experiment tests a theory of configural effects. Deviations from the relative-weight averaging model obtained in previous research (Birnbaum, 1974; Birnbaum et al., 1976) and in the first four experiments of this article are presumed to depend on the stimulus configuration. Implications of a configural-weight theory (Birnbaum, 1974) are explored in the fifth experiment.

Weight and Scale Value

Figure 1 shows how effects of the source on scale value and weight can be separated and analyzed in a relative-weight model. The three examples show hypothetical predictions assuming that the source affects weight only (A1 & B1), scale value only (A2 & B2), or both (A3 & B3).[1] Panels A1, A2, and A3 plot

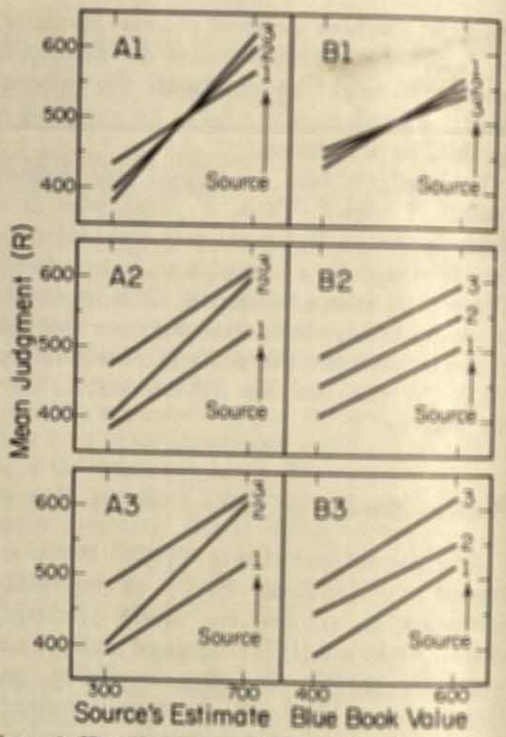

Figure 1. Hypothetical results assuming that sources affect weight only (Panels A1 & B1), scale value of the source's estimate only (A2 & B2), or both weight and scale value (A3 & B3). (Panels A1, A2, and A3 show mean judgments, averaged over blue book value, as a function of the source's estimate with a separate curve for each source. Panels B1, B2, and B3 show mean judgments, averaged over source's estimate, as a function of blue book value with a separate curve for each source. Note that changes in either weight or scale value of the source's estimate can affect the slopes in the A panels. Differences in slope in the B panels are not affected by changes in the scale values of the source's estimates, but depend upon the source's weights.)

[1] In all three examples in Figure 1, scale values for the blue book value were \$400 and \$600, with a weight of 2; the scale values for estimates of Source 2 were always \$300 and \$700, with a weight of 2; the weight of the initial impression was 0. In the first example (A1 & B1), the weights of Sources 1, 2, and 3 were 1, 2, and 3, respectively, and scale values remained fixed at \$300 and \$700. In the second example (A2 & B2), the weights of all three sources were 2; the scale values for Source 1 were \$450 and \$725, for Source 2 they were \$300 and \$700, and for Source 3 they were \$275 and \$550. For the third example, the weights of Sources 1 and 3 were 1, and the weight of Source 2

judged value as a function of the source's estimate with a separate curve for each source. The effect of the source's estimate, ΔR_E, that is, the change in response due to the source's estimate (averaged over blue book value), from Equation 1, will be given by the expression:

$$\Delta R_E = \frac{w}{w_0 + w_V + w} \cdot \Delta s_E, \qquad (1a)$$

where Δs_E is the range of scale values of the source's estimates. Note that the slopes in the A panels of Figure 1 will depend on both weight (w) and the range of scale values, Δs_E. The slopes are proportional to ΔR_E because the abscissa values are constant for all sources; Δs_E and w may or may not vary for different sources.

Panels B1, B2, and B3 of Figure 1 show the response plotted against the blue book value, averaged over the source's estimate, with a separate curve for each source. For the B panels, the effect of blue book value, ΔR_V, is given by the following equation:

$$\Delta R_V = \frac{w_V}{w_0 + w_V + w} \Delta s_V, \qquad (1b)$$

where Δs_V is the range of scale values of the blue book values. Note that if w_0, w_V, and Δs_V are presumed to be independent of the source, the effect of the blue book value (slope) should vary inversely with the weight of the source, w.

Change of weight only. The pattern of results in Figure 1, Panels A1 and B1, is consistent with the results of Birnbaum et al. (1976), who varied expertise (but not bias) of the source. For that experiment, Sources 1, 2, and 3 would represent low, medium, and high expertise, respectively. It was concluded that expertise affects weight, not the range of scale values, since the effects of blue book value (slopes in Panel B1) are lower for sources of higher expertise, as predicted by Equation 1b if expertise affects weight.

Change of scale value only. It seems unlikely that manipulation of the bias of a source, holding expertise constant, would affect only weight and produce the pattern of Panels A1 and B1. If the source's bias affects the scale values of the source's estimates, one would expect main effects of bias and possibly interactions between the bias of a source and the source's estimate. Figure 1, Panel A2, illustrates such a possibility. In this case, Sources 1, 2, and 3 might represent friend of the seller, independent, and friend of the buyer, respectively. At first, the increased slope for Source 2 in Panel A2 might be thought to indicate that Source 2 has greater weight. However, Panel B2 shows the weights are equal, since the curves are parallel. Parallelism implies that the effect of blue book value is independent of the source, indicating (by Equation 1b) that the sources have equal weights.

Change of weight and scale value. Panels A3 and B3 of Figure 1 indicate a pattern in which the source affects both weight and scale value. The curve with the steeper slope in Panel A3 also has the flatter slope in Panel B3.

These examples illustrate that in order to separate the influences of the source on weight and scale value, one must examine not only the effect of a source's estimate (A panels) but also the effect of another cue such as the blue book value (B panels). The effect of the source's *estimate* depends on *both* the source's weight and the range of scale values (Equation 1a and A panels). The effect of blue book value, however, provides an unambiguous constraint on the source's weight (Equation 1b and B panels). By comparing Panel A with Panel B one can tease apart the effects of source variables such as bias on weight and scale value.

Experiments 1–4: Three Models of Source Bias

Figure 2 shows three models of source bias (on the left) and an important prediction of each (on the right). All of the models are relative-weight averaging formulations and can be represented by lever and fulcrum models. The lever is an analog computer that can be used to make predictions for the three models. In each case, the scale value of the source's estimate is represented by the *location* along the lever where the weight is placed,

was 2; the scale values for Source 1 were \$450 and \$850, for Source 2 they were \$300 and \$700, and for Source 3 they were \$150 and \$550.

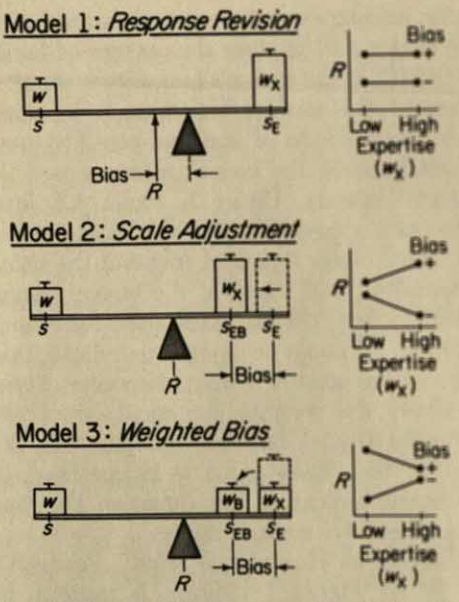

Figure 2. Three models of source bias. (Scale value, s, corresponds to a point along the lever; mathematical weight, w, corresponds to physical weight placed on the lever. Apart from the effects of bias, the response [R] would be the center of gravity, fulcrum balance. Model 1 predicts no interaction between bias and expertise. Model 2 assumes that bias affects the scale value of the source's estimate and predicts that the effect of bias increases with the increasing expertise of the source. Model 3 assumes that the source's bias and estimate are two pieces of information that are averaged to form an overall assessment. Since the relative weight of bias decreases as expertise increases, Model 3 predicts that the effect of bias diminishes with increasing expertise.)

weight corresponds to *weight*, and the response is represented by the *center of gravity* (location of the fulcrum at equilibrium).

In each model, the scale value and weight of the other information (e.g., blue book value) are s and w, the scale value of the source's estimate is represented by s_E, and the weight of the source's expertise is w_X. To represent the initial impression, the plank alone is presumed to have a weight of w_0 with a center of gravity at s_0. The change in response due to bias is shown in each figure by a comparison of solid and dashed symbols (weights or arrows). The direction of bias illustrated in the figure is negative, consistent with the source being a friend of the seller.

Model 1: Response Revision

According to the first model, bias produces a shift in the response, rather than affecting weight or scale value. As shown in Figure 2, this can be represented by the lever if the response is assumed to be the weighted average of a bias-free response, R^*, and a response effect of bias, b_B. A special case of this model can be written as follows:

$$R = \left(\frac{w_{R^*}}{w_{R^*} + w_B}\right)R^* + \left(\frac{w_B}{w_{R^*} + w_B}\right)b_B, \quad (2)$$

where w_{R^*} and w_B are the weights of the bias-free response and the bias adjustment, respectively, which are assumed to be constant, and R^* (fulcrum, or balance point not considering bias) is given by Equation 1:

$$R^* = (w_0 s_0 + w_S + w_X s_E)/(w_0 + w + w_X).$$

This model predicts no interaction between bias and any of the other factors. In particular, the effect of bias is predicted to be independent of expertise, as shown in the upper right section of Figure 2.

A more complicated version of Model 1 would allow the source's weight (w_X) to depend on both expertise and bias. The changes in weight due to bias and expertise can be estimated from the effects of blue book value (as in Figure 1). This more general model still predicts that once the weights have been estimated in this fashion, the residual effect of bias will be independent of expertise. The response revision model represents the judgment as a two-stage process in which the average value is first computed without paying attention to bias, then bias is averaged together with this implicit response.

Model 2: Scale Adjustment

The second model assumes that the bias of the source causes a shift in the value of the information provided by the source. Thus, the scale value of information from a biased source is adjusted "prior" to the integration process. Figure 2 depicts this process by showing that the source's weight is *not* placed at the scale value of the estimate, s_E, but instead at a bias-corrected value, s_{EB}, which depends on both bias and estimate. A special case of this model, which assumes that $s_{EB} = s_E + b_B$, can be written:

$$R = \frac{w_0 s_0 + w_S + w_X(s_E + b_B)}{w_0 + w + w_X}. \quad (3)$$

This scale-adjustment model predicts that the effect of bias will be greater for sources of high expertise than for sources of low expertise, since expertise (w_X) multiplies the bias correction (b_B).

A more complicated version of this model allows the weight of the source to depend on both expertise and bias and allows the corrected scale value to depend on both estimate and bias. This general version of Model 2 can be written as follows:

$$R = \frac{w_0 s_0 + w s + w_{XB} s_{EB}}{w_0 + w + w_{XB}}, \quad (4)$$

where the subscripts of w_{XB} and s_{EB} suggest that the weight of a source depends on both expertise (X) and bias (B), and scale value depends on both estimate (E) and bias (B). The more general model does not require estimate and bias to combine additively to produce scale value.

Model 3: Weighted Bias

The third general theory assumes that the source's estimate and the source's bias are both pieces of information that must be integrated to form an overall evaluation. The scale value of the source's estimate, s_E, receives a weight that depends on the source's expertise, w_X. However, the scale value of the source's bias, b_B, has a weight that depends only on bias, w_B. Thus, as the expertise increases, the source's estimate receives greater relative weight, and the source's bias receives reduced relative weight. Model 3 can be written:

$$R = \frac{w_0 s_0 + w s + w_X s_E + w_B b_B}{w_0 + w + w_X + w_B}. \quad (5)$$

Model 3 predicts that the effect of bias will be *inversely* related to the expertise of the source: As w_X increases, the relative weight of bias, $w_B/(w_0 + w + w_X + w_B)$, decreases. Model 3 can also be extended to allow the weight of the source's estimate to depend on bias, w_{XB}, or to allow the bias correction to depend on estimate and bias. Model 3 asserts that as a source grows in expertise, the judge places more weight on what the source *says* and therefore less relative weight on the correction for bias.

In sum, the three models predict that increasing expertise either increases the effect of bias (Model 2), decreases the effect of bias (Model 3), or does not interact with bias (Model 1). These differential predictions, shown on the right in Figure 2, are tested in the first four experiments.

Method

Instructions

The task was to judge the values of hypothetical used cars based on *blue book value* and/or *estimates* of value provided by sources who varied in *bias* and *expertise*. The sources of the estimates were described as people who attempted to judge the "true" value of the cars, based on a 30-minute inspection and test drive. Their relationship with the buyer or seller and their expertise in judging the value of automobiles were specified.

Source expertise. Separate paragraphs discussed the training and mechanical skill of the sources, who were described as low, medium, or high in expertise. The low-expertise source was described as a competent person who drives a car regularly and has purchased cars for himself. The medium-expertise source was a person who has taken some classes in auto shop and can make some repairs himself. The high-expertise source was described as an expert mechanic whose hobby is the repair and modification of sports cars.

Source bias. Each source was described as a friend of the buyer, a friend of the seller, or an independent. It was explained that the buyer's friend would be expected to be sensitive to his friend's desire to get a good value for his or her money and might emphasize the car's bad points. The independent was characterized as a neutral person with no relationship with the buyer or seller and no reason to under- or overestimate. The seller's friend would be concerned with the seller's desire to get as much money as possible for the car. He might be optimistic about the car and emphasize its good points.

Blue book value. The blue book value was described as a standard "fair" price that is determined by such factors as year, model, make, and mileage. It was remarked that blue book value is widely relied upon by businesses that deal in large numbers of cars, but that it would not describe individual cars.

Procedure and Designs

Each test booklet contained three pages of instructions, 20 warm-up trials, and 293 randomly ordered test trials. The test trials were constructed from the following designs:

Source estimate. A $3 \times 3 \times 5$ (Bias $\times$ Expertise $\times$ Estimate) factorial design generated 45 trials on which the only information presented was the estimate of a source whose expertise and bias were specified. The three levels of the source's bias were friend of the buyer, friend of the seller, and independent. The three

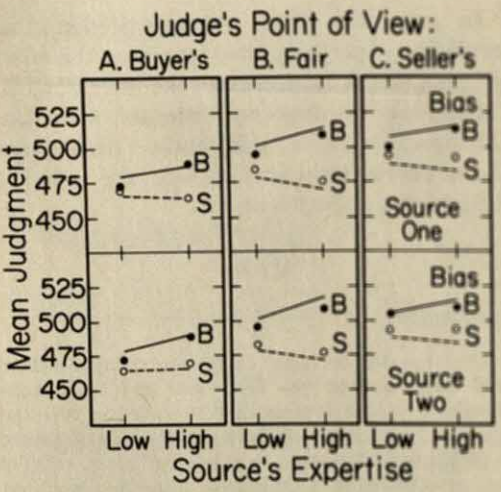

Figure 3. Mean judgment of value as a function of the source's expertise with a separate curve for each level of the source's bias. (Points are empirical means, and lines are predictions based on the scale-adjustment model, Equation 4. Solid points and lines are for friends of the buyer [B]; open circles and dashed lines are for friends of the seller [S]. Upper and lower rows of panels are for the first and second sources, respectively. Panels A, B, and C represent different points of view for the judge, Experiments 1–4.)

levels of source expertise were high, medium, and low. The five levels of estimate were \$300, \$400, \$500, \$600, and \$700.

Source estimate and blue book value. The entire $3 \times 3 \times 5$ source-estimate design was factorially combined with the four levels of blue book value: \$350, \$450, \$550, and \$650. The resulting $(3 \times 3 \times 5) \times 4$, (Bias × Expertise × Estimate) × Blue Book Value, design yielded 180 trials on which the information consisted of a source's estimate and a blue book value.

Two source estimates. Two separate $2 \times 2 \times 2$ source-estimate designs were factorially combined to generate 64 trials ($[2 \times 2 \times 2] \times [2 \times 2 \times 2]$) with estimates from two sources. For both sources, the two levels of bias were friend of the buyer and friend of the seller; the two levels of expertise were high and low. The levels of estimate for the first source were \$400 and \$600; for the second source, they were \$300 and \$700.

In addition, there were four trials in which only the blue book value was presented: \$350, \$450, \$550, and \$650.

Judge's Point of View and Research Participants

All four experiments used the same test trials and warm-ups, but three different points of view were given to different groups of judges, who were instructed to identify with either the buyer, the seller, or an independent. The judges were 121 undergraduates at the University of Illinois who received extra credit in an introductory psychology course. A small number of additional students failed to follow instructions or complete the task and were excluded.

Experiments 1 and 2: Fair price. The judges were instructed to imagine that they had been hired by an "independent, unbiased assessor to estimate the 'true' value of many cars." They were told to neither overnor underestimate "true worth." Experiment 1, with 51 participants, was conducted a year before the others. Experiment 2, with 19 judges, was a replication of Experiment 1 conducted contemporaneously with Experiments 3 and 4. The data for Experiments 1 and 2 were analyzed separately and were virtually identical; consequently, the data were pooled.

Experiment 3: Buyer's price. The buyer's task was to estimate the highest price for which he or she would recommend buying a car. The 26 judges in Experiment 3 were instructed to imagine that they were acting as the agent of someone who would be buying used cars and to ask themselves, "What is the *maximum* amount I would advice *paying* for each car?"

Experiment 4: Seller's price. The seller's task was to estimate the lowest price for which he or she would recommend selling a car. These 25 judges were instructed to imagine that they were acting as the agent of someone who would be selling used cars and to ask themselves, "What is the *minimum* amount I would advise *accepting* for each car?"

Results

Figure 3 shows the interaction between expertise and bias for the two-source design, plotted for comparison with the predictions on the right in Fig. 2. Mean judgments of value are plotted as a function of the source's expertise, with solid points for the friend of the buyer (B) and open circles for the friend of the seller (S). As expected, judged values are greater when the source is a friend of the buyer than when he is a friend of the seller. The upper panels are for the first source, averaged over levels of both estimates and over expertise and bias of the second source. Lower panels are for the expertise and bias of the second source.

Panels A, B, and C show the results for the buyer's point of view (Experiment 3), the independent, "fair" point of view (Experiments 1 & 2), and the seller's point of view (Experiment 4), respectively. Comparing the three panels shows that the mean judgments are greater for estimates of the "lowest selling price" (Panel C) than they are for the "highest buying price" (Panel A).

All six panels show a divergent interaction: As expertise increases, the difference due to the source's bias increases. Divergence is also characteristic of plots made for individual judges. Analysis of variance tests of the inter-

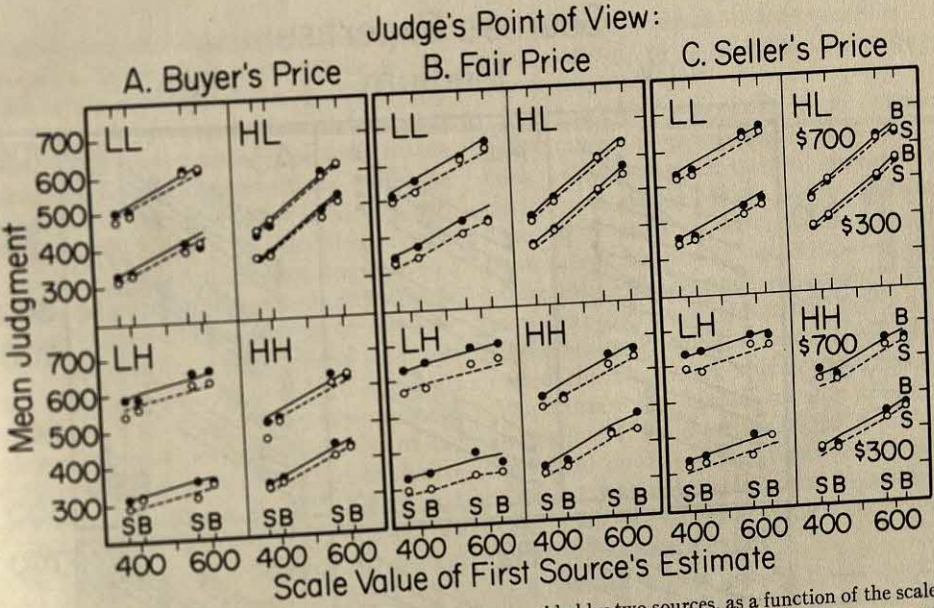

Figure 4. Mean judgment of value based on estimates provided by two sources, as a function of the scale value of the first source's estimate. (The four abscissa values represent scale values for estimates of $400 or $600, by a friend of either the buyer [B] or seller [S]. Upper panels represent data for second sources of low expertise [L]; lower panels are for second sources of high expertise [H]. Open circles and solid points represent second sources who are friends of the seller and friends of the buyer, respectively. Lines represent theoretical predictions based on scale-adjustment theory, with dashed lines for friends of the seller, Experiments 1–4.)

action between bias and expertise of the second source yielded $F(1, 25) = 12.7$, $F(1, 69) = 36.6$, and $F(1, 24) = 10.2$ for buyer's, fair, and seller's points of view, respectively. This divergence is predicted by the scale-adjustment model (Model 2 of Figure 2), which assumes that the source's bias causes a shift in the scale value of the information he provides. The solid and dashed lines plotted on Figures 3–5 represent predictions for Model 2 of Figure 2 (Equation 4). Model analyses will be discussed in a later section.

Figure 4 shows the results for all 64 two-source combinations, with a separate set of four panels for each point of view of the judge. Each panel within Figure 4 contains letters representing the expertise of the first and second sources, respectively. Thus the upper, left panel of each figure represents the results for two low-expertise sources (LL); the upper right panel shows the results for a high-expertise first source and a low-expertise second source (HL). The abscissa is spaced according to the scale value of the first source's estimate, derived from Equation 4. The letters S and B on the abscissa show the scale values for the first source's estimates (either $400 or $600), provided by a friend of the seller (S) or buyer (B), respectively. The four separate curves within each panel are for levels of bias and estimate of the second source. Solid points and lines are used for second sources who are friends of the buyer; open circles and dashed lines are used for friends of the seller.

There are four important results in Figure 4 that are common to all points of view, characteristic of the majority of individual subjects, statistically reliable, and (importantly) relevant to evaluation of the models. First, the effect of a source's estimate is greater for sources of higher expertise. Within each set of panels, proceeding from the upper left to the upper right corresponds to an increase in the expertise of the first source. Since the first source's estimate is on the abscissa, the increase in slope represents an increase in the effect of this estimate. The vertical separation between the two curves of the same type (either solid or dashed) represents the effect of the second source's estimate, which was

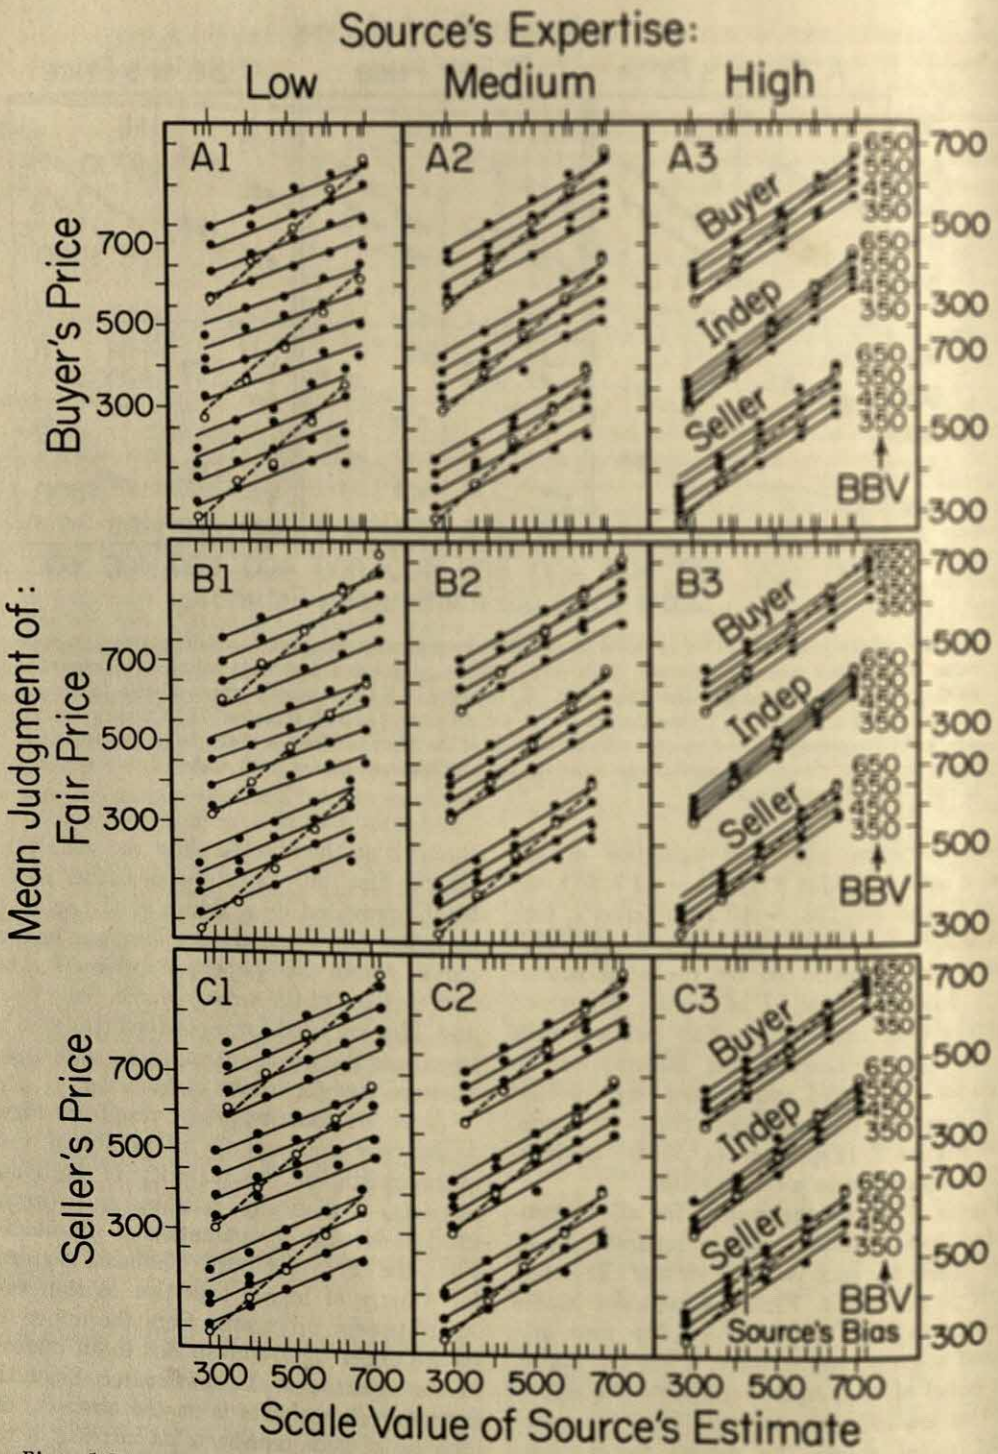

Figure 5. Mean judgment as a function of the source's estimate and blue book value. Panels A1–A3: Judgments of the highest price a buyer should pay (Experiment 3). Panels B1–B3: Judgments of "true" value (Experiments 1 & 2). Panels C1–C3: Judgments of the lowest acceptable selling price (Experiment 4). (Columns represent different levels of source expertise. Data for biased sources have been shifted vertically on the ordinate, $250 up for the friend of the buyer and $250 down for the friend

either \$300 or \$700. Dropping from an upper panel to a lower one corresponds to an increase in the expertise of the second source. Accordingly, the spread between the curves is greater in the lower panels. The tests of the Expertise × Estimate interactions for the first source yielded $F(1, 25) = 60.7$, $F(1, 69) = 239.2$, and $F(1, 24) = 45.0$ for the buyer's, fair, and seller's price judgments, respectively.

Second, the effect of either source's estimate is *inversely* related to the expertise of the *other* source. Thus, as the slopes increase from left to right, the spreads decrease. As the spreads increase from the upper to the lower panels, the slopes decrease. For the Expertise of the First Source × Estimate of the Second Source interaction, the *F*s were $F(1, 25) = 56.0$, $F(1, 69) = 329.3$, and $F(1, 24) = 59.6$ for buyer's, fair, and seller's price conditions, respectively.

Third, the effect of bias varies *directly* with the expertise of the same source. Note that the spread between open and filled circles (effect of the bias of the second source) is greater in the lower than the upper panels (when the expertise of the second source is greater). Fourth, the effect of bias varies *inversely* with the expertise of the other source. The spread between solid and dashed curves is *smaller* in the panels on the right (HL and HH, where the first source is high in expertise) than in the panels on the left. For the Expertise (of the first source) × Bias (of the second source) interaction, the *F* values were $F(1, 25) = 6.8$, $F(1, 69) = 26.2$, and $F(1, 24) = 21.3$, for buyer's, fair, and seller's price, respectively. Thus, bias interacts with expertise in the same fashion as estimate, consistent with the scale-adjustment model.

Figure 5 shows the results for the source-estimate and blue book value designs for all three points of view. The abscissa of each figure is spaced according to least squares estimates of the scale values of the source's estimate, based on Equation 4. The three leftmost notches on the abscissa, facing into each panel, show the positions of the scale values for an estimate of \$300 provided by a seller's friend, an independent, or a buyer's friend, respectively.

The solid points represent mean judgments based on a source's estimate and the blue book value (indicated next to curves). Open circles and dashed lines denote judgments based only on a source's estimate (no blue book value). Panels 1, 2, and 3 show the effects of increasing the source's expertise. It can be seen that proceeding from left to right, the slopes increase but the vertical spreads between the blue book value curves decrease. The curves for biased sources are shifted vertically (\$250 up for the friend of the buyer and \$250 down for the friend of the seller). The ordinate on the far right is labeled for these two; the left ordinate is labeled for the independent-source data.

A portion of the present experiment (independent sources, fair price condition) replicates Experiment 1 of Birnbaum et al. (1976). These 60 data points give virtually identical results to those of the earlier experiment.

The effects in Figure 5 for the source-estimate and blue book value design are highly reliable relative to the error terms. More importantly, similar effects occur in each experiment, providing evidence of replication. Statistical analyses confirm these graphic interpretations. For example, for the fair point of view, the $F(2, 138)$ for the main effect of bias was 102.3. The divergent interaction between bias and expertise, predicted by the scale-adjustment model, has an $F(4, 276) = 15.9$. The interaction between expertise and estimate yields $F(8, 552) = 122.5$. The theory that the weight of a source depends on expertise predicts the Expertise × Blue Book Value interaction, in which the effect of the blue book value is inversely related to expertise, $F(6, 414) = 114.7$. The effect of the blue book value also depends on the bias of the source, $F(6, 414) = 4.4$, and on the Expertise × Bias interaction, $F(12, 828) = 7.3$, consistent with the

---

of the seller [right-ordinate scales]. Separate curves are drawn for different levels of blue book value [BBV]. Open circles represent judgments based on one source's estimate only. Lines represent predictions based on scale-adjustment theory. Abscissa spacing represents fitted scale values, which are permitted to depend on source bias and estimate [Experiments 1–4].)

interpretation (Equation 4) that the source's weight depends on both bias and expertise.

The data for the blue book value and source-estimate design are consistent with the following: Scale value depends not only on the source's estimate but also on the source's bias. This theory (scale adjustment) explains the divergent Expertise × Bias interaction. Bias also affects the weight of a source, as evidenced by the differences in slope in Figure 5 for different bias–expertise combinations, in conjunction with the corresponding changes in the spread of the curves. Appendix A considers a complex alternative to all three models in Figure 2, which attempts to explain the effect of bias without scale adjustment. The complex model makes several incorrect predictions.

Confidence Intervals

The point size in Figures 4 and 5 is such that the solid and open circles contain a confidence interval of at least ±1 probable error in most cases. For Experiments 1 and 2, 42% of the means had standard errors less than \$6.00, 64% were less than \$8.00, 80% were less than \$10.00, and 93% were less than \$12.00. For Experiment 3, 35% of the means had standard errors less than \$8.00, 51% were less than \$10.00, and 63% were less than \$12.00. For Experiment 4, 50% of the standard errors were less than \$8.00, 58% were less than \$10.00, and 60% were less than \$12.00. These data seem quite neat, considering that adding another point size vertically on either side would include a 95% confidence interval in most cases.

Analyses for Individual Judges

Examination of data indicated that the group means are representative of the data for the vast majority of single judges. For example, four Expertise × Bias interactions were drawn separately for each of the 70 judges of Experiments 1 and 2. Model 2 predicts that the effect of bias should vary directly with the source's expertise and inversely with the expertise of the other source. The two-source design allows two examinations of each of these two predictions. Of the 70 subjects, 66% had either three or four interactions of the predicted form. Only 7 subjects had a greater number of inconsistent patterns than consistent patterns; 2 of these appear to have reversed the directions of bias for buyer and seller. Only 2 subjects had the pattern predicted by Model 3. Given that each point was the average of only 16 judgments and the fact that the Expertise × Bias interactions are predicted to be small, the small number of "deviant" judges doesn't provide evidence for the existence of large subgroups obeying different models. Of the 280 figures, 206 were of the predicted form, the same proportion for each prediction, suggesting that the group means are highly representative of individual data.

Model Analyses

Choice among models. Model 2 is vastly superior to Models 1 and 3, since it correctly anticipates the divergent Expertise × Bias interaction, in which the effect of bias is magnified by expertise. Accordingly, the 289 data points for each experiment were separately fit to Equation 4 by means of a computer program, which used Chandler's (1969) STEPIT subroutine to minimize the sum of squared model–data discrepancies.[1]

The data of Experiments 1 and 2 were analyzed separately with nearly identical results, showing excellent cross-validation of both the model and parameter values upon replication. The data of Experiments 1 and 2 are pooled in the analyses reported here.

Weights and scale values. The scale value for the blue book value of \$550 was set to its monetary value, and the weight of the blue book was arbitrarily set to 1.0. There were 29 parameters to estimate, 9 weights for the sources (Expertise × Bias), 15 scale values (Estimate × Bias), 3 scale values for the blue book value, and a weight and a scale value for the initial impression.

The weights of the initial impression were small: .08, .08, and .10 for the buyer's price, fair price, and seller's price, respectively. Scale

[1] We thank Ron Hinkle for checking our parameter estimates from STEPIT against those obtained by his subroutine, BLACKBOX, which uses an improved minimization algorithm.

Table 1
Estimated Weights and Scale Values for the Scale-Adjustment Model

Variable	Judge's point of view: Buyer's price — Source's bias: Buyer	Independent	Seller	Fair price — Source's bias: Buyer	Independent	Seller	Seller's price — Source's bias: Buyer	Independent	Seller
Estimated weights of sources[a]									
Source's expertise									
Low	.68	.59	.71	.76	.62	.84	.90	.76	.92
Medium	1.35	1.32	1.32	1.43	1.62	1.62	1.42	1.49	1.46
High	2.22	3.21	2.25	2.63	4.33	2.77	2.76	3.45	2.44
Estimated scale values[b]									
Source's estimate									
$300	307	291	271	330	301	267	330	297	276
$400	407	397	370	430	401	364	428	404	380
$500	515	491	464	538	502	459	534	504	474
$600	608	594	562	633	601	561	629	607	576
$700	692	686	647	729	691	651	723	702	671

[a] Each entry in the upper portion of the table is the estimated weight for each source as a function of the source's expertise and bias. A separate analysis was performed for each point of view. The weight of the blue book value was set to 1.0. For example, the weight of the high-expertise friend of the buyer was 2.22 for Experiment 3 (buyer's price).

[b] Each entry in the lower portion of the table is the estimated scale value as a function of the source's estimate and the source's bias. For example, the largest scale value for Experiment 3 (buyer's price), $692, was for an estimate of $700 by a friend of the buyer. For Experiment 4 (seller's price), the same estimate from the same source had an estimated scale value of $723.

values for the initial impression were related to the point of view: 243, 368, and 390 for buyer's, fair, and seller's price, respectively. Estimated scale values for the blue book were 339, 446, 550, and 648 for the fair point of view (values were very similar for the other points of view). The least squares estimates of weights and scale values are shown in Table 1.

Table 1 shows that the weights depend mostly on expertise, but tend to be larger for the independent source of high expertise and possibly smaller for the low-expertise, independent source. This pattern of weights appeared in all experiments. The weights for the 9 sources estimated from the least squares analysis are consistent with weights estimated graphically, from the effect of blue book value, using the method of Figure 1.

The scale values depend on three factors: estimate, source's bias, and judge's point of view. For example, a $500 estimate provided by an independent has a scale value of only 491 from the buyer's point of view, 502 from the fair price point of view, and 504 from the seller's point of view. If the $500 estimate in the fair price condition is provided by a friend of the buyer, the scale value jumps to 538, compared with only 459 if the estimate is provided by a friend of the seller.

Fit of the scale-adjustment model. Predictions of the model are shown in Figures 3, 4, and 5 and come very close to the data. The square roots of the mean squared model–data discrepancies were 12.15, 10.16, and 11.16 for buyer's, fair, and seller's price, respectively. Hence, the average discrepancy between the model and sample means is not much larger than the expected discrepancy (standard error) between sample and population means.

Figures 3, 4, and 5 show that Model 2 makes the following correct predictions: First, it correctly predicts the divergent Expertise × Bias interactions. These interactions are best seen in Figure 3, where they have been plotted for comparison with Figure 2. The

Expertise × Bias interactions can also be seen in Figure 4. Figure 5 does not permit one to see this prediction easily, but when data for the Blue Book Value × Source Estimate design were plotted as in Figure 3, a similar pattern was evident: The greater the expertise, the greater the effect of bias.

Second, Model 2 gives a good description of the slopes and spreads of the curves in Figures 4 and 5. The greater the expertise of a source, the greater the effect of that source's estimate and bias and the *less* the effect of the estimate and bias of another source (Figure 4) or of the blue book value (Figure 5).

Third, Model 2 gives a good account of the single-source data (open circles and dashed lines in Figure 5), which cross the curves for different levels of blue book value.

Deviations of fit. The deviations from the model should be taken seriously, since each circle in Figures 4 and 5 contains a fair-sized confidence interval. The model predicts that the curves in each set in Figure 5 should be parallel. Instead, the interaction between estimate and blue book value shows a divergence to the right for the buyer's and the independent's points of view, $F(12, 300) = 6.6$ and $F(12, 828) = 11.2$, respectively. Similar divergence was also obtained by Birnbaum et al. (1976) and can be described by a configural-weight model, which assigns greater weight to the lower estimate. A configural-weighting revision of the scale-adjustment model is tested in Experiment 5.

There is also a hint of a higher order configural effect. When the judge has the seller's point of view and the buyer provides a low estimate, the effect of blue book value is greater than predicted (points are spread wider than predictions), as though the buyer's low estimate receives reduced weight. When the buyer provides a higher estimate, the data points are compressed, as if the buyer receives higher relative weight for providing an unexpected estimate.

In summary, the results of Experiments 1–4 are generally consistent with the scale-adjustment model (Model 2) of Figure 2. Deviations are small but regular. Consequently, Experiment 5 explores these deviations, testing modifications of Model 2 that allow the weight of an estimate to depend on the stimulus configuration.

Experiment 5: Test of Configural Weighting Models

Experiment 5 addressed three issues raised by the first four experiments. First, although the between-subjects manipulation of point of view did affect scale values in a predictable fashion, the pattern of weights did not support a prior conjecture that the weight of a source would be greater when the source's bias matched the judge's point of view (Table 1). Interpretation of between-subjects results requires extreme caution, however, since the effects of a variable such as point of view may depend on the establishment of a context of comparison for the individual judge. Consequently, Experiment 5 allowed each judge to experience all three points of view.

Second, the fact that the effect of a source's estimate and bias varies inversely with the number and expertise of other sources would also be consistent with a linear-weighted model in which the effective weight of a source varies with the *difference* between the source's weight and some function of the total absolute weight instead of the *ratio;* that is, the effective weight would be $w - f(\Sigma w)$ instead of $w/\Sigma w$. In order to test this linear-weight model against relative-weight averaging models (such as Model 2), it is necessary to have at least two sources that each take on more than two levels of expertise. Therefore, Experiment 5 was designed to compare the success of the relative-weight model versus the linear-weight model.

Third, systematic deviations of fit appeared in Experiments 1–4. These deviations appear consistent with previous results obtained by Birnbaum (1972, 1973, 1974) and by Birnbaum et al. (1976). The deviations in Experiments 1–4, although convincing, were not large enough to warrant detailed theoretical analysis. In previous tests of averaging models, deviations from parallelism were found to be related to the range (maximum–minimum) of scale values within the set of stimuli to be integrated. Consequently, Experiment 5 contained greater variation in the range of scale values within sets in order to permit a better examination of the deviations from the averaging model.

Configural-Weight Theory

To account for stimulus interactions, simple configural-weight theories have been proposed and tested by Birnbaum, Parducci, and Gifford (1971), Birnbaum (1972, 1973, 1974), and Birnbaum and Veit (1974). The scale-adjustment model (Model 2 of Figure 2) can be modified to allow for configural weighting. The simplest configural-weight theory was termed the range model. According to this model, the relative weight of a stimulus depends in part on the rank of that stimulus in the configuration of stimuli to be integrated on a given trial.

For two stimuli, the range model may be written:

$$R = \frac{w_0 s_0 + w_1 s_1 + w_2 s_2}{w_0 + w_1 + w_2} + \omega_P |s_1 - s_2|, \quad (6)$$

where ω_P is the weight of the configural, or range ($|s_1 - s_2|$) effect, which, in the present case, would presumably depend on the judge's point of view. Note that when $s_1 > s_2$, the relative weight of s_1 can be written:

$$\frac{w_1}{w_0 + w_1 + w_2} + \omega_P. \quad (7)$$

However, when $s_1 < s_2$, the relative weight of s_1 can be written:

$$\frac{w_1}{w_0 + w_1 + w_2} - \omega_P. \quad (8)$$

The range model assumes that the effective relative weight of a stimulus depends on the rank of its scale value in the set of stimuli to be combined. As a limiting case, when ω_P equals the relative weight of a stimulus, the range model can become a maximum or minimum (conjunctive or disjunctive) model, depending on the sign of ω_P. The model implies that the response varies linearly with the range of scale values, holding mean scale value constant.

If the two stimuli are two estimates provided by different sources, if the weight depends on the expertise and bias of the source (e.g., $w_1 = w_{X_1B_1}$), and if the scale value depends on the source's estimate and bias (e.g., $s_1 = s_{E_1B_1}$), then Equation 6 becomes an extension of the scale-adjustment model (Model 2 of Figure 2). This configural-weight model adds a single parameter, ω_P, to account for the effects of the judge's point of view.

Note that ω_P in Equation 7 is the amount of relative weight taken from the lower valued stimulus and given to the higher. If ω_P is negative, weight is added to the lower valued stimulus, yielding a divergent stimulus interaction. Such an interaction might be expected in the buyer's point of view. A convergent interaction (positive ω_P) might be expected in the seller's point of view, since the larger of two estimates should receive greater weight.

Method

The instructions, stimuli, and procedure were similar to those of Experiments 1 through 4. The chief differences were as follows: (a) Each judge was exposed to all three points of view via instructions and then judged all of the 146 stimulus combinations separately under each point of view. (b) Descriptions of the levels of expertise were modified to provide five levels. (c) The experimental designs in Experiment 5 permitted assessment of previously untested predictions of the models.

Experimental Designs

The trials selected were a subset of a $(5 \times 3 \times 9) \times (5 \times 3 \times 9)$, First Source (Expertise $\times$ Bias $\times$ Estimate) $\times$ Second Source (Expertise $\times$ Bias $\times$ Estimate) factorial design. The complete design would have required 18,225 trials; therefore, six smaller factorial designs involving these six variables were selected to test particular implications of the models. These designs are shown in Table 2 and described below.

Estimate $\times$ Estimate. Two related $(1 \times 1 \times 4) \times (1 \times 1 \times 4)$ factorial designs investigated the hypothesis that the configural weight of the lower scale value depends on the point of view of the judge. In both designs, both sources were medium in expertise; the levels of estimate for Source 1 were \$350, \$450, \$550, and \$650; and the levels of estimate for Source 2 were \$300, \$400, \$600, and \$700. In one design, the first source was a friend of the buyer and the second was a friend of the seller; in the other design, the biases were reversed.

Bias $\times$ Bias. The design was a $(1 \times 3 \times 2) \times (1 \times 3 \times 2)$, in which both sources were medium in expertise; the three levels of bias for both sources were friend of the buyer, independent, and friend of the seller; the estimate of Source 1 was either \$350 or \$650; the estimate of Source 2 was either \$300 or \$700. The purpose of the Bias $\times$ Bias design was to investigate the hypothesis that when a source provides an estimate contrary to what one would expect from that source's bias, the weight of that estimate is increased.

Bias $\times$ Expertise. Two related designs reexamined the predictions of Model 2 that expertise amplifies the effect of bias (and estimate) in the same source and

Table 2
Two-Source Designs in Experiment 5

Design	First source			Second source		
	Expertise	Bias	Estimate	Expertise	Bias	Estimate
$Est_1 \times Est_2$ (BS)	1 (Med)	1 (B)	4	1 (Med)	1 (S)	4
$Est_1 \times Est_2$ (SB)	1 (Med)	1 (S)	4	1 (Med)	1 (B)	4
Bias × Bias	1 (Med)	3	2	1 (Med)	3	2
$Bias_1 \times Exp_2$	1 (Med)	3	2	5	1 (I)	1 ($500)
$Bias_1 \times Exp_1$	5	3	2	1 (Med)	1 (I)	1 ($500)
Exp × Exp	5	1 (I)	1 ($300)	5	1 (I)	1 ($650)

Note. Each entry represents the number of levels of the factor listed above the column. The product of the entries in each row gives the number of cells in each design. For example, the first row indicates that an Estimate (Est) × Estimate design consisted of 16 trials in which the first source was a medium-(Med) expertise, friend of the buyer (B) who provided one of four estimates, and the second source was a medium-expertise friend of the seller (S) who provided one of four estimates. The last row shows that the Expertise (Exp) × Expertise design contains 25 cells in which the expertise of each source could attain one of five levels, the first source was an independent (I) who gave an estimate of $300, and the second source was also an independent with a $650 estimate.

diminishes the effect of bias (and estimate) in a second source. A (1 × 3 × 2) × (5 × 1 × 1) factorial design used five levels of expertise (very low, low, medium, high, or very high) for the second source, an independent who gave an estimate of $500, combined with a medium-expertise first source, with three levels of bias of Source 1 (S, I, B) and two estimates, $350 or $650. A second factorial design, a (5 × 3 × 2) × (1 × 1 × 1), was identical, except that it shifted the five levels of expertise to the first source and held the expertise of the second source at medium. The purposes of these two designs were to constrain the estimates of weights and to replicate the Bias × Expertise × Estimate interactions of Experiments 1–4.

Expertise × Expertise. To test the averaging model against the linear-weighted model requires more than two levels of expertise for two sources. Hence, a (5 × 1 × 1) × (5 × 1 × 1) factorial design was employed in which the five levels of expertise for each source were very low, low, medium, high, and very high. The bias of each source was "independent." The estimate of the first source was $300, whereas the second source gave an estimate of $650.

The designs employing two sources generate a total of 153 stimulus sets, 15 of which are shared by two designs, leaving 138 distinct two-source test trials. These designs constrain all of the two-way interactions and many of the three- and four-way interactions among the six variables. In addition, 8 trials were produced by a single-source design, in which only one source provided an estimate. The design was a 2 × 2 × 2, Expertise × Bias × Estimate, factorial design, in which the two levels of expertise were low and high, the two levels of bias were friend of buyer and friend of seller, and the estimate was either $300 or $700.

Procedure

The 146 trials were printed in random orders in booklets in three sets, with additional instructions and 10 warm-up trials reminding the judge of the point of view for each set. Judges were permitted to work at their own paces, completing the 438 experimental trials in about 2 hours.

Research Participants

The judges were 60 undergraduates at the University of Illinois who received extra credit in introductory psychology for participating. Ten students served in each of the six possible orders of three points of view.

Results

The upper panels of Figure 6 show mean judgments as a function of the estimate provided by a medium-expertise seller with a separate curve for each level of estimate provided by a medium-expertise buyer. The lower panels plot judgments as a function of the buyer's estimate, with a separate curve for each level of seller's estimate. Panels A to C represent the judge's point of view. Lines in Figures 6–9 are predictions of the range model (Equation 6), an extension of Model 2 of Figure 2, using a different value of w_p for each point of view. This model is discussed in a later section.

Figure 6 shows a striking result. Whereas the models considered in Experiments 1–4 predict parallel curves in each panel, the curves in Figure 6 are systematically non-parallel. Furthermore, the interactions are related to the judge's point of view. The curves

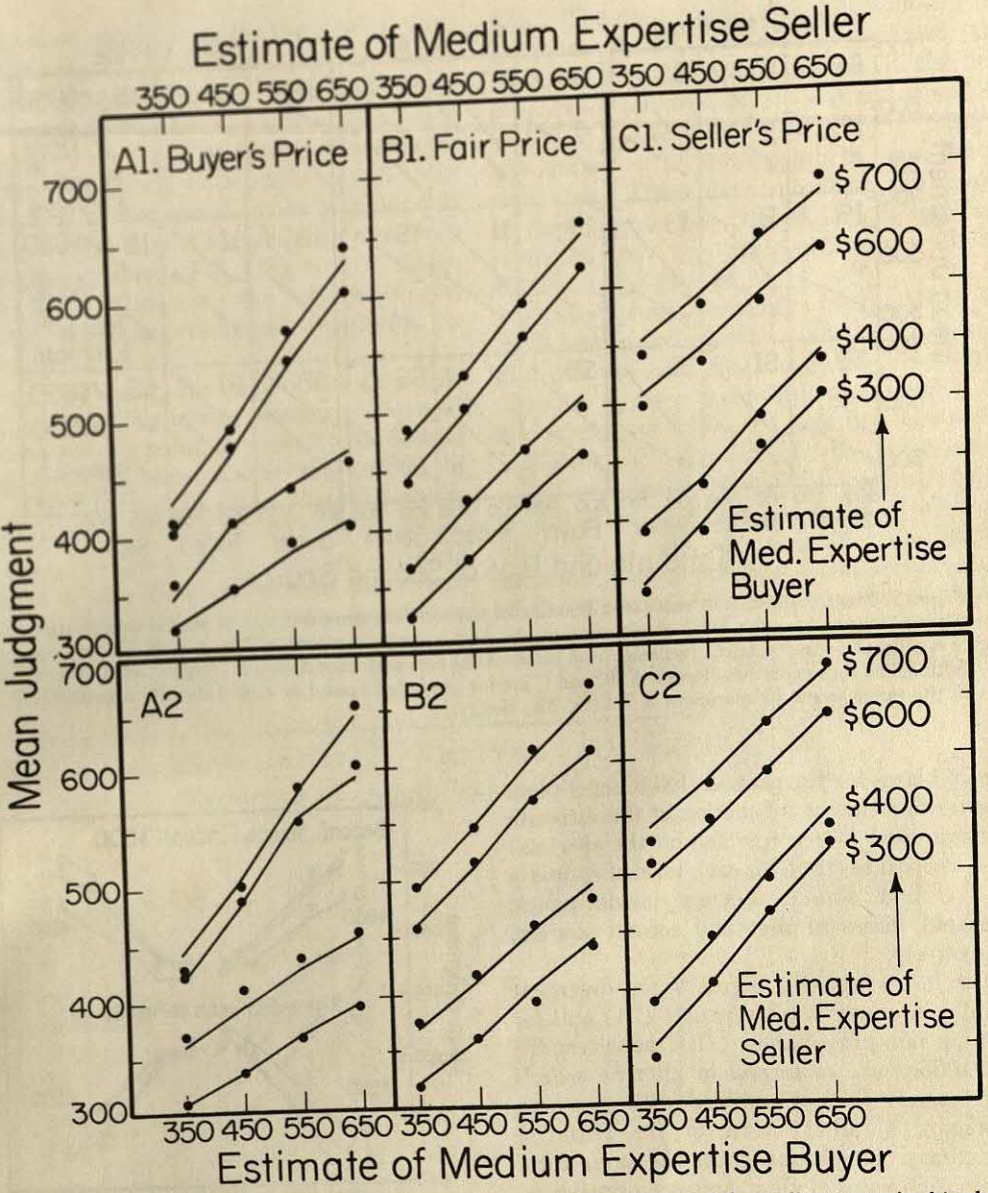

Figure 6. Upper panels: Judgment of value as a function of the estimate of the medium-expertise friend of the seller with a separate curve for each estimate of the medium-expertise friend of the buyer. Lower panels: Judgment of value as a function of the estimate of the buyer's friend (on the abscissa) with separate curves for the estimates of the seller's friend. (Panels A, B, and C are for the judge's point of view. Lines represent predictions of the range model [Experiment 5, Estimate × Estimate designs].)

diverge for the buyer's point of view and for the fair price point of view; however, they converge for the seller's point of view. It is as if the judge places greater weight on the lower estimate when identifying with the buyer and places greater weight on the higher estimate when identifying with the seller. The three-way interaction of Point of View × First Estimate × Second Estimate yielded Fs(18, 1062) = 11.8 and 11.3 for the two panels of Figure 6.

Figure 7 shows Estimate × Estimate interactions with a separate panel for each combina-

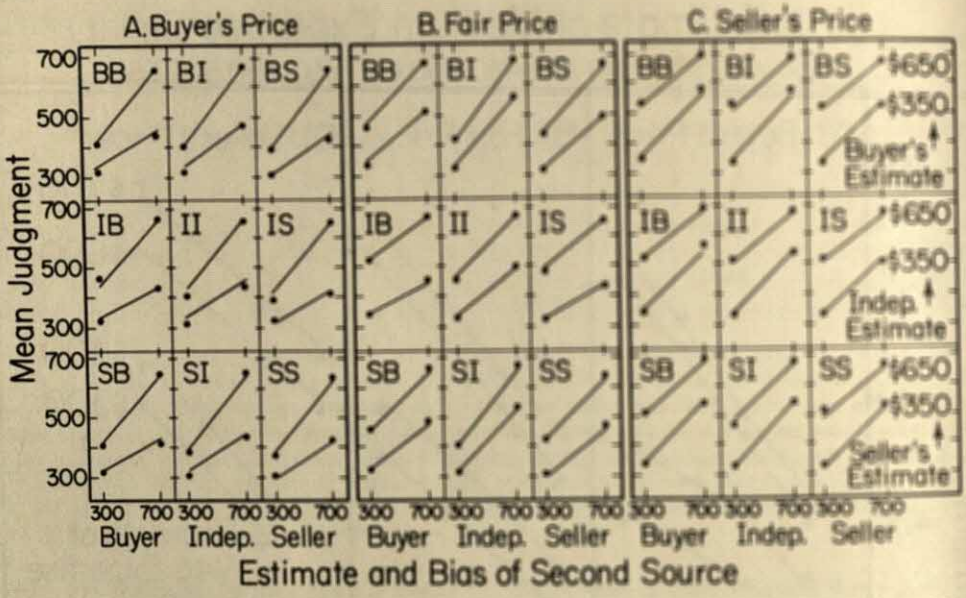

Figure 7. Mean judgment of value as a function of the estimate provided by the second source, with a separate curve for each level of estimate of the first source. (Letters within panels [B = buyer; S = seller; I = independent] represent the biases of the first and second sources, respectively, who were both medium in expertise. Panels A, B, and C are for the judge's point of view. Lines show predictions of the range model [Experiment 5, Bias × Bias design].)

tion of biases for the sources. Each panel plots mean judgments as a function of the estimate of the second source (plotted on the abscissa) with a separate curve for each level of estimate of the first source. Letters inside panels represent biases of first and second sources, respectively.

The interactions in Figure 7 are divergent for all nine buyer's price panels (7A) and for all nine fair price panels (7B); however, the interactions are *convergent* in all nine seller's price panels (7C). Combined with the data of Figure 6, all 11 tests of the Estimate × Estimate interaction show the same form within each point of view. Assuming a relative-weight averaging model (all of the models in Figure 2 predict parallelism), it would be extremely unlikely to obtain 11 divergent or convergent interactions, all of the same type, within each point of view.

The group means are highly representative of data for individual judges. For example, 58 of 60 judges show the divergent Estimate × Estimate interaction of Figure 7 for the buyer's point of view; 48 judges show divergence for the fair price of view, and 40

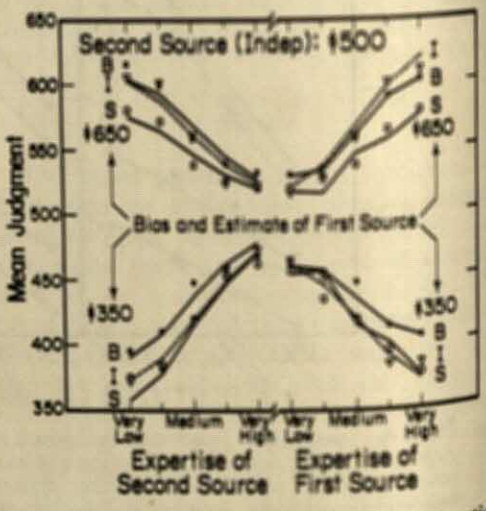

Figure 8. Left: Mean judgment of value as a function of the expertise of the independent second source (who said $500), with a separate curve for each level of bias (B = buyer; S = seller; I = independent) and estimate of the first source. Right: Mean judgment of value as a function of the expertise of the first source. (The second source was a medium-expertise independent who said $500. Lines show predictions of the range model [Experiment 5, Bias × Expertise designs].)

judges show convergence for the seller's point of view. Hence, these data provide strong evidence that the Estimate × Estimate interactions of Experiments 1–4 and of Birnbaum et al. (1976) are "real" and, most importantly, that the Estimate × Estimate interaction can be reversed by manipulating the judge's point of view. For the data of Figure 7, this three-way interaction yielded $F(2, 118) = 39.7$. Thus, some modification of the relative-weight models, such as configural weighting, is necessary.

Figure 8 shows the results for the Bias × Expertise × Estimate designs, averaged over the judge's point of view. These designs retested the implications of the models of Figure 2. The left panel of Figure 8 shows that as the expertise of the second source increases, the effects of the bias and estimate of Source 1 (the distances between the curves) decrease. The Expertise × Bias interaction yielded $F(8, 472) = 6.1$, and the Expertise × Estimate interaction had an $F(4, 236)$ of 226.1. The right-hand panel shows that as the expertise of the first source increases, the effects of bias and the estimate of the first source increase, $F(8, 472) = 4.8$ and $F(4, 236) = 158.2$, respectively. The general pattern was similar for all three points of view, drawn separately. These data reconfirm the results of Experiments 1–4; this pattern of results is predicted by the scale-adjustment model (Model 2 of Figure 2).

Figure 9 shows the results for the Expertise × Expertise design, with a separate panel for each point of view. The abscissa represents the expertise of an independent source who gave an estimate of \$650; the separate curves are for levels of expertise of the independent source who said \$300. The positive slopes indicate that judged value increases with the expertise of the source giving the higher estimate. Judged value decreases as a function of the expertise of the source giving the lower estimate.

Averaging models predict a nonparallel set

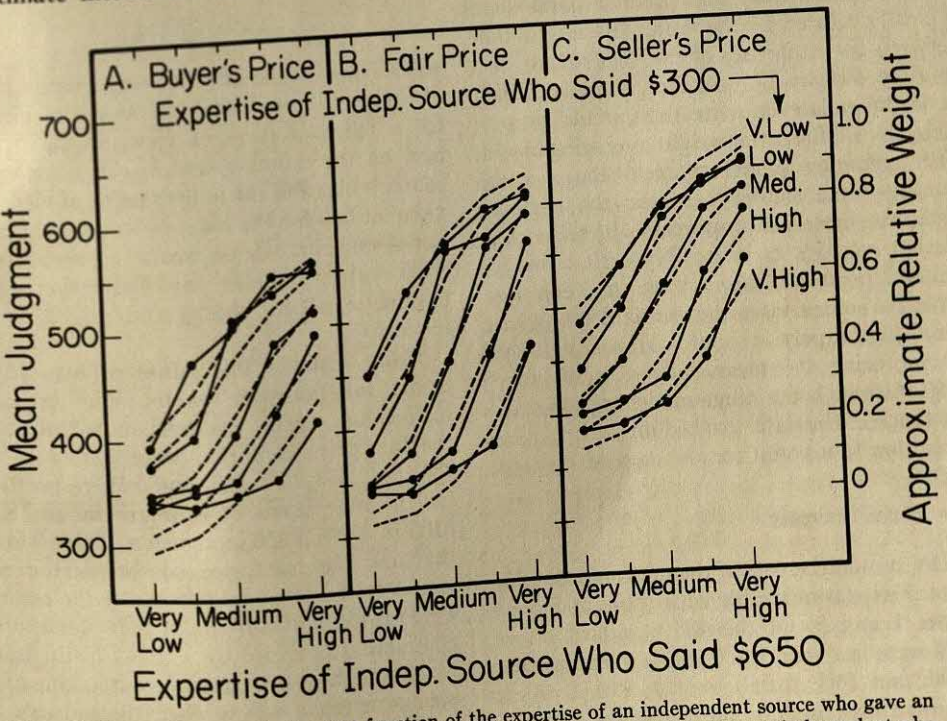

Figure 9. Mean judgment of value as a function of the expertise of an independent source who gave an estimate of \$650, with a separate curve for each level of expertise of the first source, an independent who said \$300 (Panels A, B, and C are for buyer's, fair, and seller's points of view, respectively. Dashed curves show predictions of the range model. Right ordinate represents an approximate scale of relative weight [Experiment 5, Expertise × Expertise design].)

Table 3
Estimated Bias Adjustments for the Range Model

Point of view	Source's bias		
	Buyer	Independent	Seller
Buyer's price	8.79	6.39	−33.50
Fair price	20.22	0	−34.76
Seller's price	24.26	1.26	−14.79

Note. Each entry is the estimated value of b_{BP} in Equation 9: $s_{EBP} = s_E + b_{BP}$. The estimated values for s_E are \$322, \$352, \$410, \$451, \$511, \$563, \$620, \$662, and \$703 for the nine levels of estimate ranging from \$300 to \$700. For example, the largest value in the table (24.26) means that the scale value for an estimate provided by a friend of the buyer raises the scale value \$24.26 when the judge takes the seller's point of view. Thus, an estimate of \$500 has a scale value of \$511 + \$24 = \$535 in this condition. The negative numbers show that when a friend of the seller provides the estimate, the scale value is reduced. The value for the independent source in the fair price condition was set to 0.

of curves that bulge in the middle. An opposing linear-weights theory that predicts parallelism is clearly refuted by the data. The interaction between the expertises of the two sources has an $F(16, 944) = 29.7$. In fact, the data pinch in at the ends even more than would be predicted by a differential-weight averaging model. The averaging model predicts that as the expertise of a source increases, the response should asymptotically approach the scale value of that source's estimate. Note that for the buyer's point of view, when a very low-expertise source rates the car at \$300, even a very high-expertise source reporting \$650 cannot bring the mean judged value above \$550. Although the range model approximates the shape of the data (dashed lines), it requires a revision to account for the data of Figure 9.

Confidence Intervals

The standard errors of the means for Experiment 5 were comparable with those of Experiments 1 and 2. Of the 483 standard errors, 37% were less than \$6.00, 64% were less than \$8.00, and 76% were less than \$10.00. As in the other experiments, the size of the standard error correlates with the range of estimates. The point size in Figure 7 contains a fair-sized confidence interval; however, note that the ordinate scales in Figures 6, 8, and 9 are expanded, so that a point size does not necessarily contain a large confidence interval.

Model Analyses

Range model. The range model (Equation 6) was fit to the data by means of a computer program utilizing the STEPIT subroutine, designed to minimize the sum of squared data-model discrepancies over all 483 (161 × 3) cells in the experiment. Except for the configural-weight parameter, w_P, the model is a form of scale-adjustment model (Model 2 of Figure 2).

The number of parameters required to estimate scale values was reduced by the simplifying assumption that the scale value of a biased source's estimate is an additive function of a scale value depending on the estimate alone and a bias parameter depending on the source's bias and the judge's point of view:

$$s_{EBP} = s_E + b_{BP}, \tag{9}$$

where s_{EBP} is the effective scale value for an estimate, E, provided by a source of bias, B, for a judge of point of view, P; s_E depends only on the estimate, and b_{BP} depends on the source's bias and the judge's point of view. The value of b_{BP} for the independent source in the fair price point of view was set at zero. Hence, scale values require the estimation of 17 parameters, 9 for the s_E and 8 ($3 \times 3 - 1$) for b_{BP}.

Table 3 shows the values of bias adjustments for the scale values. The estimated scale values, s_E, for the independent source for the fair price condition were 322, 352, 410, 451, 511, 563, 620, 662, and 703, respectively, for the nine levels of estimate ranging from \$300 to \$700 in \$50 increments. Table 3 shows that for the fair price condition, the scale values would be about \$35 less if the estimate were provided by a friend of the seller or about \$20 more if provided by a friend of the buyer. As one might expect, the absolute value of the bias adjustment is less when the source's bias matches the judge's point of view, as if the judge views a source of his or her own point of view as less biased.

To permit examination of how weights for

different sources might depend on point of view, a different weight was estimated for each type of source in each point of view. Thus, 45 weights, w_{XBP}, were estimated for the $5 \times 3 \times 3$, Expertise $\times$ Bias $\times$ Point of View combinations. The weight of the low-expertise independent in the fair price condition was set to 1.0, leaving 44 parameters to be estimated.

The least squares estimates of weights are shown in Table 4. The general pattern of weights in Experiment 5 is similar to that of Experiments 1–4. The ratio of the weight of high- to low-expertise independents for the fair price condition is 6.78, not far from the corresponding value of 6.98 for Experiments 1 and 2. The weights depend mostly on expertise, with the greatest weights being for independents of very high expertise. For the buyer's point of view, the buyer's weight exceeds that of the seller for all levels of expertise. For the seller's point of view, the friend of the seller receives greater weight than the corresponding buyer for the very high-expertise source. There is thus a very slight hint of support for the notion that biased sources receive relatively higher weight when the judge shares the source's bias, but the evidence does not seem decisive.

In addition, separate weights and scale values for the initial impression and separate values of ω_P, the configural weight parameter, were permitted for each point of view. These 9 parameters, plus 44 source's weights, plus 17 for scale values make a total of 70 parameters to be estimated to describe the data in Figures 6–9.

The estimated scale values of the initial impressions were 281, 308, and 413, with weights of .30, .15, and .24, for buyer's, fair, and seller's price, respectively. The values of the configural-weight parameter, ω_P, were $-.194$, $-.066$, and .055 for the buyer's price, fair price, and seller's price, respectively.

The predictions of this model are shown in Figures 6–9. The model is an extension of Model 2 of Figure 2, with only one elaboration—the configural-weight effect to allow for Estimate $\times$ Estimate interactions. Considering that only one additional parameter is used for each point of view, the range model gives a very good account of the data in Figure 6 and a good account of the data of Figure 7. The root mean squared errors were 6.83 and 10.40 for Figures 6 and 7, respectively. The overall sum of squared deviations was 61,497 over 483 points, yielding a root mean squared deviation of 11.28. This value was 13.08, 10.23, and 10.30 for the buyer's, fair, and seller's price conditions, respectively.

Table 4
Estimated Weights of Sources for the Range Model

Source's bias	Expertise of source: Very low	Low	Medium	High	Very high
Buyer's point of view					
Buyer	.91	.80	2.42	4.52	6.42
Independent	1.00	1.53	3.05	5.70	9.98
Seller	.76	.45	2.39	2.63	4.90
Fair price point of view					
Buyer	.66	.77	1.40	3.22	4.89
Independent	.47	1.00	2.68	6.78	17.57
Seller	.43	.38	1.50	2.34	4.13
Seller's point of view					
Buyer	.96	1.43	2.37	4.10	4.95
Independent	.75	1.22	2.62	5.44	10.20
Seller	.85	1.08	2.25	3.47	6.35

Note. Each entry is the least squares estimate of weight for each type of source under each condition. The weight of the low-expertise independent source in the fair price condition was set to 1.0. For example, the table shows that when the judge takes the seller's point of view, the very high-expertise friend of the seller has greater weight (6.35) than the very high-expertise friend of the buyer (4.95).

The range model would have been a great success had the data of Figure 9 not been collected. When a very high-expertise, independent source gives an estimate of \$300 and a very low-expertise independent source gives an estimate of \$650, the mean judgment for the buyer's point of view is \$342, compared with a prediction of \$292, a deviation of about \$50. The range model makes this extremely low prediction because the relative weight of the \$650 estimate is so low in this case (.09) that when the negative value of $\omega_P(-.194)$ is added to it, the effective relative weight of the \$650 estimate becomes negative. In other words, the best-fit value of ω_P for the entire

experiment (including the data of Figures 6 and 7) is a poor value for the data of Figure 9.

To examine the effective relative weights, the right ordinate of Figure 9 has been labeled from 0 to 1. Since the scale values are approximately equal for the independent sources from different points of view, and since the weight of the initial impression is so small, the right-ordinate values can be read off to give the approximate relative weight of the $650 estimate for each point in Figure 9.

Revised configural-weight theory. The assumption of the range model that the configural change of weight is independent of relative weight appears inconsistent with the data of Figure 9. The model was revised to incorporate the principle that the amount of *decrease* in absolute weight is directly proportional to the absolute weight apart from the configural effect. Weight taken from one stimulus is given to another. Hence, if a source's estimate loses weight, it does so in proportion to its original weight; if a source's estimate gains weight, it does so in proportion to the weight of the other source's estimate. Thus, there is a conservation of absolute weight: The loss of one source is another source's gain.

The revised configural-weight model is a scale-adjustment model (Equations 4 & 9). It is distinguished from the range model (Equation 8) in that the configural change of weight operates on absolute rather than relative weight. The weights are given by the following equation:

$$w_{XDFE} = w_{XDF} + w_F \sigma_{FFE}, \qquad (10)$$

where w_{XDFE} is the effective absolute weight of an estimate; w_{XDF} is defined as in the range model; w_F is the configural-weight parameter; $\sigma_E = 1$, if the estimate is the largest in the set, $\sigma_E = -1$ if it is the smallest, and $\sigma_E = 0$ otherwise. By definition, $\rho_{FE} = w_{XDF}$ if $w_F \leq 0$; otherwise, $\rho_{FE} = w_{X\cdot D\cdot F}$, where $w_{X\cdot D\cdot F}$ is the absolute weight of the other source. Thus, a source loses weight in proportion to its original value but increases by taking the weight lost by the other source.

This modified configural-weight model (Equations 4, 9, & 10) provides a great im-

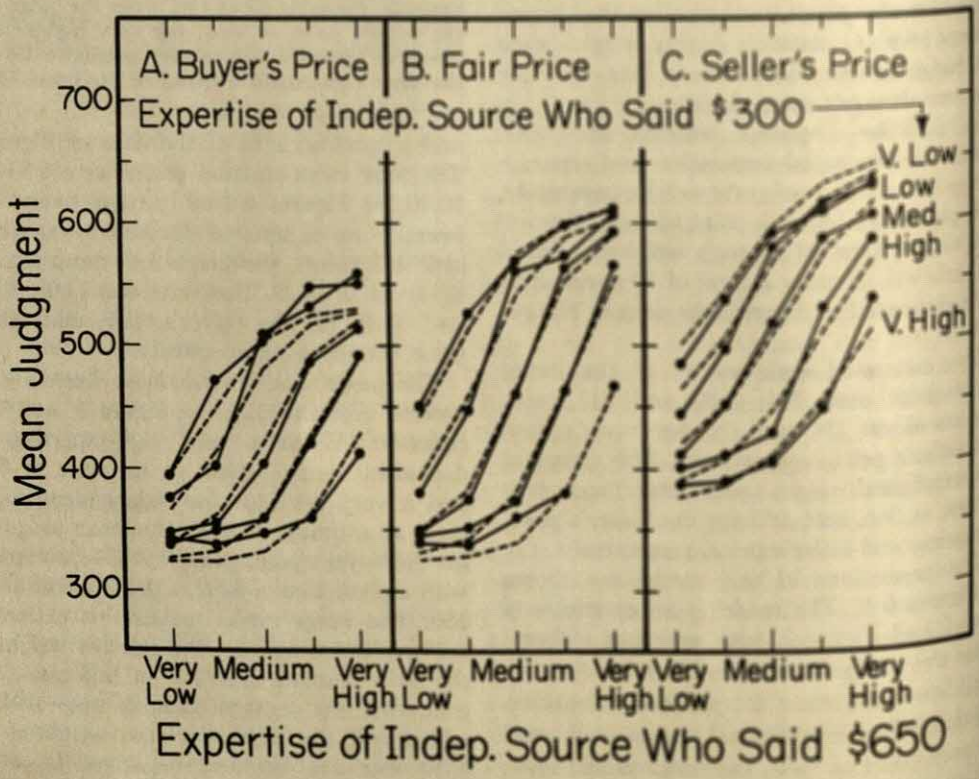

Figure 10. Data of Figure 9 with predictions (dashed curves) of revised configural-weight theory.

provement over the simple range model (Equations 4, 6, & 9), though it uses the same number of parameters. The total sum of squared deviations over all 483 cells was reduced from 61,497 to 48,333, yielding a root mean squared error of 10.00. The improvement in fit was greatest for the Expertise × Expertise design (Figure 9), where the root mean squared mistake was reduced from 17.24 to 13.09. The fit was also noticeably better for the Expertise × Bias design (Figure 8). Fit was about the same or slightly better in the other designs.

Figure 10 shows the fit of the improved configural-weight model to the Expertise × Expertise design. Solid points are empirical means; dashed curves represent predictions. As can be seen by comparing Figures 9 and 10, the revised configural-weight theory gives a superior description of these data, especially for the fair price point of view.

The estimated scale values and bias parameters of this configural model were similar to those of the range model. The pattern of estimated weights was also similar, except that the weights always increased with expertise for this model (an improvement), and the range of weights increased (especially for the independent sources). The values of ω_P were −.385, −.155, and .130 for the buyer's, fair, and seller's points of view, respectively. An extension of the configural-weight model is discussed in Appendix B.

Differential-weight theory. In differential-weight theory, the weight of a stimulus is permitted to depend on the estimate. For the present data, the weight would be required to depend on point of view as well. The most complex, scale-adjustment, differential-weight model allows an increment in weight to depend on three factors: bias, point of view, and estimate. There are 81 values of the weight increment, 9 of which (for the independent, fair price conditions) were set to 0, leaving 72 weight parameters to be estimated (69 more than the configural-weight model). Two versions were tried: In one version the added increment in weight was independent of w_{XBP}; in the other it was proportional to w_{XBP}. Scale adjustment was allowed, in accordance with Equation 9. Neither of these differential-weight models described the data of Figure 9 as well as the configural-weight model (Equation 10). The best-fitting differential-weight model can be written as follows:

$$w_{XBPE} = w_{XBP}(1 + \theta_{BPE}), \qquad (11)$$

where θ_{BPE} is the weight increment and w_{XBP} is defined as in Equation 10. The root mean squared deviations for the Expertise × Expertise design were 16.8, 16.9, and 14.3 for the buyer's, fair, and seller's price judgments, respectively, compared with 15.3, 10.6, and 12.9, respectively, for the modified configural-weight theory (Equation 10).

The differential-weight theory requires a relationship between the shape of the curves in Figure 9 and their approach to the scale values. The curves should "bow over" only as they asymptotically approach the scale values (Birnbaum, 1973; Riskey & Birnbaum, 1974). As can be seen from Figure 9, however, the curves bow over long before reaching the estimated scale values. For example, the highest point in Figure 9B was predicted to be $641 by the differential-weight averaging model, compared with $610 for the data and $608 for the prediction of the configural-weight model (Equation 10). This deviation from the averaging model is similar to that obtained by Birnbaum (1973) and by Riskey and Birnbaum (1974). Since the differential-weight model of Equation 11 uses nearly twice as many parameters yet fits the data of Figure 9 worse, configural-weight theory seems preferable.

Discussion

The purpose of this research is to examine theories of how judges (who may be biased) combine information from sources who vary in their ability to report the truth (expertise) and their motivation to distort it (bias). By representing these processes with mathematical models, it becomes possible to test experimentally among explicit theories of social judgment.

Experiments show that certain algebraic representations cannot account for the judgments. Additive and constant-weight averaging formulations have been tested and rejected in previous studies of information integration (T. Anderson & Birnbaum, 1976; Birnbaum,

1972, 1973, 1974, 1976; Birnbaum et al., 1976). The present data are in agreement with these previous studies in refuting additive and constant-weight averaging models in favor of some form of configural, relative-weight averaging model.

The present research goes beyond previous work to test three distinct forms of the relative-weight averaging model that attempt to explain the effects of the source's bias. In one, the effect of the source's expertise does not alter the effect of his or her bias; in another, expertise magnifies the effect of bias; in the third, expertise diminishes the effect of the source's bias. The data give a clear indication that the response-revision and weighted-bias models can be rejected. The retained model, scale-adjustment, which predicts that expertise will magnify the effects of bias, makes additional, independent predictions that are fulfilled by the data. By making these correct predictions, the status of the model as a representation of source effects is enhanced. The present research also extends the investigation to examine configural-weight theories of how the judge's point of view affects the weights and scale values of estimates from biased sources.

Source Bias and Expertise

The scale-adjustment model of Figure 2 (Model 2) correctly predicts that the source's expertise will amplify the effect of the source's bias, a prediction that was confirmed in all five experiments. The model does not imply that experts are necessarily *judged* to be more biased, only that the *effect* of bias will be greater for sources of greater expertise. It is as if the judge, hearing that the seller's friend provided an estimate of $500, thinks, "That means $470," before averaging the information, giving greater weight to the estimate provided by the source of greater expertise.

The weight of an estimate depends mostly on the source's expertise; however, weight also varies with bias. A consistent trend across all experiments is that the unbiased source (the independent) of high expertise tends to have greater weight than either biased source of the same expertise.

It is important to note that the effect of bias on weight and its effect on scale value can work in tandem or in opposition in any given instance. Perhaps this would explain the seeming contradictions in research on attitude change for the effects of source's trustworthiness, or bias (see McGuire, 1968). Bias is both a signed variable (plus or minus) in its effect on scale value and an *absolute* variable in its effect on weight. For example, a biased source (e.g., a scientist employed by a utility company using nuclear reactors) might produce larger attitude change in favor of his message than an unbiased source if he said, "Nuclear reactors are unsafe." On the other hand, the effect of this message on the impact of other messages (weight) might be less than that of an unbiased source of the same expertise who gave the same message.

The data are suggestive, but by no means conclusive, on two other weighting effects. First, a source may receive extra weight for making an estimate that would not be expected on the basis of his or her bias. Second, the weight of a biased source may be greater if the judge is of the same point of view as the source.

Judge's Point of View

The judge's point of view consistently affects the scale values and the value of the initial impression: The values tend to be lower for the buyer's point of view and higher for seller's point of view. Perhaps the buyer's and seller's price estimations reflect persuasive judgments, meant as the opening round for bargaining. Interestingly, the absolute value of the bias adjustments in the scale values are less when the source's bias matches the judge's point of view, as if the judge perceives a compatible source to be less biased.

The effects of point of view are best represented in Experiment 5, which used a within-subjects design. This experiment showed that the weight of the lower estimate is greater for the buyer's point of view and that the weight of the higher estimate is greater for the seller's point of view. The fair price judgments were intermediate, but showed the divergent interaction characteristic of the buyer's point of view. Similar divergence was also obtained for fair price judgments in Experiments 1 and

2 and by Birnbaum et al. (1976), who obtained fair price judgments. Perhaps undergraduates tend to identify with the consumer under the fair price condition.

A modified configural-weight theory (a simple extension of the range model) gives a good account of this change of weight across points of view. The configural-weight theory uses just one additional parameter, besides the basic structure of Model 2 of Figure 2, to represent the configural effect of point of view.

Comparison of Configural- and Differential-Weight Theories

In configural theories, stimulus parameters depend on the stimulus pattern. Hence, the *higher* or *lower* estimate receives extra weight in the seller's or buyer's point of view, respectively. On the other hand, differential-weight theories assume that weight depends on stimulus magnitude, a seemingly context-free theory. In actuality, differential-weight theory requires (implicitly) a contextual theory that assigns the weights as a function of the context of the entire distribution of weights and scale values presented. For the present study, $400 would be a low estimate, deserving of a large weight from the buyer's point of view.

In contrast, configural-weight theory would not declare a $400 estimate to be low, *except in comparison with the other estimate of the same car*—that is, except with respect to the *within-set context* (Birnbaum et al., 1971). Thus, $400 would be a low estimate if the other stimuli are greater, but it would be high if the other estimates were lower. It is the *relationships* among estimates of the same car that define the configural weights. Thus, configural-weight theory takes the implicit context theory of differential weighting and extends it explicitly to the immediate (within-set) context of stimuli presented on each trial.

Configural-weight theory can be represented by means of a fulcrum and balance analogue, as in Figure 2. The configural parameter, ω, represents the proportion of weight that, depending on the point of view, is taken from either the higher or lower stimulus and given to the other. Differential-weight theory can also be represented by the lever and fulcrum; however, each location on the lever has a different weight associated with it. In addition, differential weighting requires a complete remapping of weights to locations for each point of view, using many more parameters than the configural-weight models.

Differential weighting may be required for certain situations in which multidimensional social stimuli vary in both weight and scale value simultaneously (e.g., T. S. Anderson & Birnbaum, 1976). Differential weighting is an extremely powerful curve-fitting device, one that requires special experimental designs to test. When appropriate designs have been employed, differential-weight models have failed to account for the data (Birnbaum, 1973; Riskey & Birnbaum, 1974). Judgments of morality fail to show the compensatory effects predicted by nonconfigural averaging theories: Given that a person has committed a very bad deed, there appears to be no number of good deeds that will make the person's judged morality approach the same high asymptote as if the person had done only good deeds. Similarly, the data of Figure 9 suggest that from the buyer's point of view, if a low-expertise source says $300, no level of expertise of the $650 estimate will compensate to bring the judged value above $550. For the present interactions, the simple configural-weight models provide a more elegant, accurate, and theoretically appealing description of the interactions.

Concluding Comments

This research investigates information integration under conditions in which the relevant variables can be manipulated, and it attempts to discover principles that explain the results. The hope is that principles that apply in controlled experiments are characteristic of basic psychological processes that have applicability to a wide range of judgmental phenomena. Results of experiments in a large number of domains encourage the hope that a reasonably small set of premises may account for a large array of data. Previous research has shown that the same principles of source expertise can be applied to intuitive numerical predictions, ratings of likableness, and judgments of the value of used cars. We are currently investigating the generality of

the principles of bias discovered here to see if they account for judgments of probable guilt in simulated court cases.

The present research suggests that a simple algebra can account for the complex effects of bias in information integration. Judgments can be represented by the center of gravity of a lever. Information can be represented by weights placed at various locations along the lever. The location, or scale value, of the information depends on the source's communication. This location is adjusted to account for the source's bias and the judge's point of view. The weight of a source's communication depends mostly on the source's expertise, but diminishes if the source is biased. In addition, judges appear to increment the weight of the communication most consistent with their own bias, or point of view.

Given these rules of operation, the lever is an analog computer, or model, that will reproduce the judgments obtained in these experiments. When a model can give a qualitative account of a variety of predictions, its plausibility is increased. It may then be used as a measuring device to study the effects of other variables on its parameters. With this Archimedian lever, a fulcrum, and a place to stand, we hope to raise our understanding of human judgment.

Appendix A

An alternative to all three of the models of source bias presented in Figure 2 is a differential-weight model:

$$R = \frac{w_0 s_0 + ws + w_{XBE} s_E}{w_0 + w + w_{XBE}},$$

in which the weight of an estimate, w_{XBE}, depends on expertise, bias, and estimate, but the scale value is independent of bias. This model assumes that a high estimate provided by the buyer's friend receives greater weight then if the seller's friend had made the same estimate. Consequently, the judged worth would be greater for the buyer's high estimate than for the seller's. Similarly, a low estimate is assumed to receive greater weight if it is provided by the seller's friend than if provided by the buyer's friend; consequently, judged worth would still be greater for the buyer's than the seller's estimate.

This differential-weight model cannot describe the present data. It makes three incorrect predictions for effects that are correctly predicted by the scale-adjustment model. First, it predicts that if w_0/w_{XBE} is near zero, the effects of *both* bias and expertise should be very small in the source-estimate designs, where blue book value is not presented, since $w_{XBE}/(w_0 + w_{XBE}) \approx 1$. In contrast, Equation 3 predicts that the Expertise × Estimate interaction should be small but the effect of bias should be maximal, since if $w_0/w_X \approx 0$ for all w_X, then

$$\frac{w_X(s_E + b_B)}{w_0 + w_X} \approx s_E + b_B.$$

The data for the source-estimate designs (open circles in Figure 5) show a small Expertise × Estimate interaction and a large effect of bias. The average effect of bias is \$76.6 in the source-estimate design of the fair price condition, compared with \$46.6 when blue book value is also presented. The differential-weight model incorrectly predicts that the effect of bias should have been larger when blue book value is presented.

Second, the differential-weight model predicts that there exists some level of estimate for which bias has no effect, contrary to the data. Third, the differential-weight model predicts a complex four-way interaction between expertise, bias, estimate, and blue book value that did not materialize in the predicted form. Consequently, differential weighting alone cannot explain the effect of bias—scale adjustment appears to be necessary.

Appendix B

It seems intuitively reasonable that if a source gives an estimate that would not be expected on the basis of his bias and the other estimate, he might receive greater weight. For example, if a *friend of the seller* gave an estimate below the blue book value, his estimate might receive greater weight.

To investigate this hypothesis, the data of Experiment 5 were fit using the following equation:

$$w_{XBPE} = w_{XBP} + \omega_P \sigma_E \rho_{PE} + \alpha_{PB} \beta_B \sigma_E \delta_{PBE},$$

where w_{XBPE} is the absolute weight of an estimate, E, by a source of expertise, X, and bias, B, from a point of view, P; w_{XBP} is the configural free weight, as in Equation 10; α_{PB} is the estimated configural-weight parameter that expresses the magnitude of the expectancy-contrast effect; ω_P, σ_E, and ρ_{PE} are defined as in Equation 10; $\beta_B = -1$ if the source is a seller, $\beta_B = 0$ if the source is an independent, and $\beta_B = 1$ if the source is a buyer; $\delta_{PBE} = w_{XBE}$ if $\alpha_{PB}\beta_B\sigma_E \leq 0$, and otherwise δ_{PBE} equals the configural free weight of the other source.

The product $\beta_B \sigma_E$ will be positive when either (a) a buyer provides the higher estimate or (b) a seller provides the lower estimate—instances in which the source seems to deserve extra weight for doing the unexpected. It will be negative when either a buyer provides the lower estimate or a seller provides the higher (i.e., when the source's estimate is expected). Notice that δ_{PBE} and ρ_{PE} make a decrease in weight proportional to the weight to be decreased.

Figure 7A, Panel IB shows that when the buyer gives an estimate of \$300, the effect of the independent's estimate is greater than predicted, as if the buyer lost weight. Figure 7A, Panel IS, shows that when the seller says \$300, the effect of the independent is decreased relative to the predictions of the range model.

For the buyer's point of view, the α_{PB} weights for the buyer and seller are −.08 and .20, respectively; for the fair price point of view, the values are close to zero, −.04 and −.01, respectively; and for the seller's point of view, they are .05 and .11, respectively. Thus, it appears that for either biased point

of view, the seller receives extra weight for making the lower estimate. The friend of the buyer receives additional weight for the seller's point of view when he provides the higher (unexpected) estimate; however, for the buyer's point of view, the buyer receives greater weight for providing the lower estimate. The near-zero values for the fair price condition may reflect the fact that the fit of Equation 10 was already quite good in that condition (see Figure 7B).

The expectancy weight modification reduces the overall sum-of-squares discrepancies from 48,333 to 44,267, an improvement of 8.4% over Equation 10. The root mean squared deviation was 9.57. Improvements were greatest for the Expertise × Expertise, Bias × Bias, and Expertise × Bias designs for the buyer's point of view.

Self-Consciousness, Self-Attention, and Social Interaction

Allan Fenigstein
Kenyon College

Two experiments were conducted to test the effects of self-focused attention on positive and negative social interactions. In the first study, the behavior of dispositionally high and low publicly self-conscious women was examined in an interpersonal situation involving rejection by a group. It was hypothesized that persons high in self-consciousness, being more aware of how they are perceived by others, would be more sensitive and react more negatively to the rejection than those low in self-consciousness. The predictions were confirmed. In Experiment 2, female subjects were presented with favorable or unfavorable feedback in the context of an interview, and self-attention was experimentally manipulated by exposing half the subjects to their images in a mirror. Self-awareness increased the negative response to the negative evaluation and tended to increase the positivity of the positive evaluation. The implications of self-awareness theory for the social self and social interaction are discussed.

Everyday observations as well as theoretical approaches to social behavior suggest that in the presence of others, one is apt to become self-conscious, that is, aware of the self as a social object that can be observed and evaluated by others. Goffman (1959) has argued quite persuasively that when one is attending to and involved in an ongoing interaction, that interaction can proceed smoothly and naturally; but if one is engaged in self-focused thought during that interaction, then concern is shifted away from what is being said toward whether what one says will be received favorably or unfavorably.

Argyle (1969) also proposes that self-consciousness, conceived of as the activation of the "self-system," produces a decreased concern with evaluating the behavior of others and an increased concern with the personal and public assessment of one's own behavior. It follows that when the self-system remains dormant, relatively less thought is given to one's own behavior or its effects on others. Similarly, Duval and Wicklund (1972) have experimentally demonstrated that a state of self-focused attention causes one to engage in self-examination and self-evaluation.

Underlying all of these approaches to self-consciousness are several common, but crucial, assumptions: (a) During a social encounter, attention may be directed either toward or away from the self. (b) When attention is self-directed, the person becomes *conscious* of the *self* as an object of attention to others; conversely, when attention is directed away from the self toward external stimuli, there is little consciousness of the self as a social object. And (c) a major consequence of self-consciousness is an increased concern with the presentation of self and the reactions of others to that presentation.

Determinants of Self-Attention

Self-focused attention has several sources, both situational and dispositional. It can be brought about through the presence of others, whereby the person becomes cognizant of the

This article is partially based on a doctoral dissertation submitted to the Graduate School of the University of Texas at Austin. The manuscript was written while the author was on leave at the University of Virginia. The author is grateful to Arnold Buss for his support and advice through all phases of the research and to the reviewers for their helpful comments on an earlier draft. Portions of this article were presented at the annual convention of the American Psychological Association, San Francisco, August 1977.

fact that others perceive him or her as an object (Carver & Scheier, 1978); or it may be the result of a reflective stimulus, such as a mirror or a tape recording of one's own voice, which is a reminder of one's status as an object (Argyle, 1969; Duval & Wicklund, 1972).

In addition to situationally induced self-attention, there may also be individual differences in the degree to which self-consciousness occurs. Argyle (1969) has theorized that persons differ in the extent to which the self-system becomes salient in the presence of others, and more recently, Fenigstein, Scheier, and Buss (1975) constructed and extensively administered a scale to measure *self-consciousness*, defined as the enduring tendency of persons to direct attention toward themselves. Factor analyses of the scale consistently yield two stable self-consciousness dimensions: *public* and *private*. The private factor is defined by an awareness of one's personal thoughts and feelings (e.g., "I'm always trying to figure myself out"). The public subscale involves an awareness of the self as a social object, that is, an awareness that others are aware of the self (e.g., "I'm concerned about what other people think of me"). In addition, a social anxiety factor emerges. Social anxiety, which is defined as discomfort in the presence of others (e.g., "I get embarrassed very easily") may be seen as a reaction to the process of self-focused attention. Previous research involving several independent samples has established that the two self-consciousness factors are only weakly correlated (Fenigstein et al., 1975; Scheier, 1976) and that the scale as a whole has considerable discriminant validity (Carver & Glass, 1976; Scheier & Carver, 1977).

Public Self-Consciousness and Social Behavior

The first study reported here had two purposes: One was to examine the effects of public self-consciousness; a second aim was to extend the study of self-focused attention into the area of social interaction. Although self-awareness has been shown to have consequences for many realms of behavior, virtually all of these behaviors have been nonsocial, involving little interaction with others. For example, heightened self-awareness has been found to facilitate task performance, increase the consistency between attitudes and behavior, decrease self-esteem, increase self-attribution (see Wicklund, 1975), and heighten the experience of emotion (Scheier & Carver, 1977)—none of these behaviors is interpersonal. Even in those studies which do involve social behavior, there is no sense of any ongoing, face-to-face interaction. In research concerning the effects of self-awareness on conformity, the reference group's opinion is simply represented on paper (e.g., Duval, 1976); and in the application of self-awareness theory to aggression, the aggressor remains essentially isolated from the target during the aggressive encounter (e.g., Scheier, Fenigstein, & Buss, 1974; Carver, 1974). It may be concluded that little is known about the consequences of self-focused attention on interpersonal behavior.

The present research focused on the role of public self-consciousness in social interaction. Publicly self-conscious persons are presumed to be susceptible to feelings of being "observed" when in the company of others (Argyle & Williams, 1969; Fenigstein et al., 1975). Believing that others are preoccupied with their appearance and behavior, these persons are always in position to infer how others perceive them and are highly sensitive to the reactions of others in a social situation.[1] Extreme examples of public self-consciousness

---

[1] The present construct of public self-consciousness should be differentiated from a seemingly related dimension called self-monitoring (Snyder, 1974). The self-monitor is also sensitive to the social behavior of others, but primarily for the purposes of monitoring and manipulating his or her own behavior so as to present an appropriate image. Although the self-monitor must obviously attend to his or her own behavior, the orientation is primarily outward toward situational requirements, as opposed to the self-conscious person, whose attention is primarily self-directed.

It may be argued that self-focused attention is related to self-monitoring: A person must observe his or her own behavior in order to create a desired impression (Goffman, 1959; Mead, 1934). But self-attention may also lead to feelings of "self-consciousness" in the popular sense of the term, that is, anxiety, discomfort, and embarrassment, which effectively disrupt, rather than facilitate, any attempt at impression management. The point is that the publicly self-conscious person may be a self-monitor or may not be. Recent investigations by the

are easily recognized. At the high end is the recently stigmatized person who, almost by definition, is an object of attention and is sensitive to the concern, disgust, or pity that is elicited from others. At the opposite end is the totally unself-conscious social boor who not only lacks any conception of how he or she appears to others but could not care less.

These speculations about the behavior of the publicly self-conscious person were tested using a relatively ubiquitous situation in social interaction: the experience of being shunned by or excluded from a group. Rejection by others may be extremely aversive. As an implicit negative evaluation, rejection has been shown to produce feelings of anxiety, embarrassment, and worthlessness (Geller, Goodstein, Silver, & Sternberg, 1974) and to decrease attraction toward the group (Dittes & Kelley, 1956; Mettee, Fisher, & Taylor, 1971). However, other studies have found that rejection does not alter liking for the group (Snoek, 1962) and may even increase one's evaluation of the others (Jackson & Saltzstein, 1959). Apparently, some persons are capable of shrugging off social rejection and seem oblivious to its effects, whereas others are very hurt by such experiences.

One factor that may help to account for these differences in reactions to rejection is the degree of awareness of the public or social self (i.e., the degree to which persons recognize and are concerned about the way they are perceived by others). For persons low in public self-consciousness, there is little awareness of how others regard them. Attention is not directed toward the self—presumably, it is consumed by the group activity or other external events—and the group's behavior in relation to the self is not relevant. Thus, the experience of being excluded from the interaction is not very salient. But highly self-conscious persons are sensitive to the issue of how they are regarded by others. For them, the group's behavior is perceived as having personal relevance, and the experience of rejection should have a clear impact on subsequent behavior.

Public self-consciousness should also affect causal explanations of the rejection. A person may make either internal attributions and assume personal responsibility for the rejection or external attributions and assume that the cause of the rejection lies with the other persons or within the situation (Pepitone & Wilpizeski, 1960). Much of the recent attribution literature has shown that causality for an event is likely to be attributed to those salient entities that attract attention and can reasonably be seen as a cause (e.g., Duval & Wicklund, 1973; Pryor & Kriss, 1977; Storms, 1973; Taylor & Fiske, 1975). Given that the social self is salient to publicly self-conscious persons and a primary target of their attention, it follows that high publicly self-conscious persons are more likely than low publicly self-conscious persons to perceive themselves as the cause of the rejection.

In a recent study, Buss and Scheier (1976) found that private self-consciousness increased the amount of causality attributed to the self, but public self-consciousness had no effect on self-attributions. Those authors reasoned that attention to one's own private thoughts and feelings is an important determinant of self-attributions, whereas focus on the self as a social object is irrelevant to such attributions. However, their research involved the use of hypothetical situations into which subjects imaginally projected themselves, and under these circumstances, it is reasonable that only private self-consciousness affected causal attributions. The present experiment involves a real social interaction, with attributions being made about behaviors that have significant social consequences, and in this case, public self-consciousness should play an important role.

In summary, the first study hypothesized that persons high in public self-consciousness would be more sensitive and react more negatively to rejection by a group, and would hold themselves responsible for the rejection to a greater degree, than those low in public self-consciousness. The major dependent variables were attraction toward and desire to affiliate

---

author have found a correlation of .24 ($N = 380$) between public self-consciousness and self-monitoring; similar results were obtained by Scheier and Carver (1977). Thus, it is unlikely that the effects of public self-consciousness can be accounted for by self-monitoring.

with the group, and causal attributions for the group's behavior.

Experiment 1

Method

The study was a 2 × 2 factorial design with one manipulated variable (rejection vs. acceptance) and one subject variable (high vs. low public self-consciousness).

Subjects

Several weeks prior to the experimental manipulation, during a period designated for this purpose, all students from courses in introductory psychology filled out a number of questionnaires. The crucial items consisted of the Self-Consciousness Scale (Fenigstein et al., 1975) and three generalized self-esteem items (e.g., "In general, I feel very good about myself").[2] Measures of self-esteem were included because previous research (Dittes, 1959; Jacobs, Berscheid, & Walster, 1971; Jones, Knurek, & Regan, 1973) suggested that it may affect reactions to rejection.

Subjects scoring in the upper and lower thirds of the distribution of public self-consciousness scores were selected. A total of 92 women participated in the experiment. Women were used because pilot studies indicated that as a group, they were more sensitive to rejection than men. Twelve subjects were dropped: eight because of suspicion expressed during the postexperimental interview and four because of failure to follow instructions. Dropouts were unrelated to experimental conditions. This left 80 subjects, 20 in each condition.

Procedure

All the experimental manipulations occurred while the subject was waiting to participate in the supposed "real" experiment. The subject arrived first at the experimental room, which was bare except for a table and chairs, and was told that several other subjects were expected and that the experiment would begin when they arrived. All subsequent participants were female confederates of the experimenter.

Before entering the "waiting room," all subjects were instructed to leave their belongings outside the room so that the experiment could begin promptly as soon as everyone had arrived. (This was actually done to prevent subjects from directing their attention and behavior toward easily available and irrelevant objects such as books or purses.)

Upon entering the room, the subject was subtly directed toward one end of a rectangular table that had one side against the wall and a chair at each end. About one minute later, the first confederate arrived and was given the same introduction as the subject. The experimenter brought another chair into the experimental room, placed it halfway between the two ends of the table, and then left. The first confederate took this seat and remained quiet. If the subject attempted to initiate a conversation, the confederate made as brief and neutral a response as possible (e.g., "yes," "no," or "I don't know").

Rejection. Approximately 30 sec later, the second confederate arrived and was told that one more subject was expected. After she took the remaining chair opposite the subject and the experimenter had left, both confederates remained quiet for about 20 sec (to establish the lack of any acquaintanceship between them). The second confederate then began a casual conversation with the first confederate, who was reticent at first but slowly became more talkative.

The first confederate played the role of a naive freshman who was living in one of the campus dorms, and the second confederate appeared to be a somewhat more experienced upper-division student who was living off campus. The conversation eventually turned to the restrictiveness of dormitory living. A recent on-campus incident concerning a resident assistant who was actually an undercover narcotics informer served as the focal point of the discussion. The younger confederate took the more conservative position, defending the school's obligation and responsibility to protect its students from the potential dangers of drugs. The other student attacked the school's intrusiveness into the private lives of students and the general authoritarian leanings of the university administration.

During the conversation, both confederates directed their comments only toward each other and ignored the subject. If the subject tried to speak, the older confederate made a brief, unenthusiastic remark such as "I see." Eye contact with the subject was minimal. The impression created by the confederates was not dislike or hostility but simply lack of interest.

Acceptance. Subjects in this group were encouraged to participate in the conversation. If the subject did not do so spontaneously, her opinions were solicited by the second confederate. Any remark uttered by the subject was attended to with interest and responded to appropriately.

Questionnaire. Five minutes after the second confederate began the conversation, the experimenter reentered the room, remarking that the "fourth subject" apparently was not coming. He went on to explain that the experiment was one of a series of studies, and all subjects would be reassigned to another part of the experiment. To facilitate the procedure, subjects were asked to provide some preliminary information based on their brief experience with each other. Questionnaires containing manipulation checks and the dependent variables were then distributed. After subjects had completed the questionnaire, they were asked a series of questions designed to determine suspicion, and then were debriefed.

Results

Covariation

Self-esteem did not correlate with the public self-consciousness variable, nor did it af-

[2] All items are available from the author upon request.

fect any of the dependent variables; thus, it was not included in the analyses. Modest correlations did exist between public self-consciousness and measures of private self-consciousness ($r = .17$) and social anxiety ($r = .24$). To measure the independent effects of public self-consciousness, 2(high vs. low public self-consciousness) × 2 (rejection vs. acceptance) analyses of covariance were used, with private self-consciousness and social anxiety as the covariates.

Manipulation Checks

Group's behavior. Subjects were asked to rate on a 7-point scale how favorably the others, as a group, behaved toward them. Rejected subjects rated the group's behavior as less favorable ($M = 3.8$) than subjects who were not rejected ($M = 5.4$). This difference was significant, $F(1, 74) = 66.4$, $p < .001$, thus establishing the adequacy of the rejection manipulation. No other effects were significant. Additional support for the success of the rejection manipulation is provided below in other analyses.

Self-Consciousness. The crucial conceptual difference between high and low publicly self-conscious persons lies in the amount of attention they focus on themselves during a social interaction. An attempt was made to assess this difference directly by asking subjects to indicate the relative percentage of time that they spent thinking about themselves during the experiment. Results showed that high publicly self-conscious subjects reported spending more time attending to themselves than low publicly self-conscious subjects: 24% vs. 9%, on the average—a highly significant difference, $F(1, 74) = 24.9$, $p < .001$. The data also suggest that the experience of rejection by others may focus attention on oneself: There was a slight tendency for rejected subjects to engage in more self-attention ($M = 18.5\%$) than accepted subjects ($M = 15\%$), but this difference was marginally significant, $F(1, 74) = 2.6$, $p < .1$.

Table 1
Number of Subjects Choosing to Affiliate with the Same Group as a Function of Treatment by the Group and Subjects' Level of Public Self-Consciousness

Self-Consciousness	Treatment	
	Acceptance	Rejection
Low	14	10
High	15	3

Note. $n = 20$ subjects per cell.

Table 2
Mean Liking for the Group as a Function of Group Treatment and Subjects' Level of Public Self-Consciousness

Self-Consciousness	Treatment	
	Acceptance	Rejection
Low	5.5	4.4
High	5.6	3.4

Note. Ratings were on a 7-point scale on which 1 corresponded to "did not like the group at all" and 7 to "liked the group very much."

Dependent Variables

Affiliation. Subjects were asked whether they wanted to continue to work with the same group or with a different group in subsequent parts of the study. Table 1 provides a frequency analysis of subjects' choices and shows that rejected subjects were less willing to continue to affiliate with the same group than nonrejected subjects, $\chi^2(1) = 12.8$, $p < .001$. Within the acceptance condition, public self-consciousness had no effect on affiliative behavior. But following rejection, high publicly self-conscious subjects chose to affiliate with the same group far less frequently than low self-conscious subjects, $\chi^2(1) = 5.6$, $p < .02$.

Attraction. Liking for the group, indicated on a 7-point scale, was considerably less in the rejection condition than in the acceptance condition (see Table 2). Within the rejection condition, public self-consciousness had a clear effect on liking: High self-conscious subjects were less attracted toward the group than low self-conscious subjects. The significance of these effects was revealed in a 2 × 2 covariance analysis that yielded a main effect for rejection, $F(1, 74) = 43.2$, $p < .001$, and a main effect for public self-consciousness, $F(1, 74) = 4.0$, $p < .05$, due primarily to the differences between the rejected subjects. This result was confirmed by a significant Public

Table 3
Mean Percentage of Self-Attributions for the Group's Behavior as a Function of Treatment by the Group and Subjects' Level of Public Self-Consciousness

Self-Consciousness	Treatment	
	Acceptance	Rejection
Low	38.7	39.2
High	55.7	49.7

Self-Consciousness × Rejection interaction, $F(1, 74) = 5.1$, $p < .05$; planned contrast indicated that public self-consciousness had no effect in the acceptance condition, but in the rejection conditions, high self-conscious subjects reacted more negatively toward the group than low self-conscious subjects $t(38) = 2.97$, $p < .004$.

Causal attributions. Subjects were asked to distribute responsibility for the way the group behaved toward them to either themselves, the others as a group, or the situation; the amount of responsibility to be attributed totalled 100%. Table 3 shows that the high, compared to the low, publicly self-conscious subjects made more causal attributions to themselves for the group's behavior across both rejection and control conditions. This finding was confirmed by a 2 × 2 covariance analysis that showed a main effect for self-consciousness, $F(1, 74) = 9.6$, $p < .01$. Causal attributions were also affected by social anxiety, $F(1, 74) = 8.3$, $p < .01$; those who became anxious in the presence of the group were more likely to feel responsible for the group's behavior than low anxious subjects. No other effects were significant.

Discussion

Experimental Findings

Rejection. Rejection by others, not surprisingly, had a strong effect on subsequent behavior. Rejected subjects perceived the group as less cooperative, liked the group less, and were less likely to continue affiliation with the group than accepted subjects. In addition, rejected subjects were somewhat more likely to focus attention on themselves during the interaction than nonrejected subjects.

For ethical reasons, rejection was manipulated in a deliberately passive manner: Other group members failed to show an interest in the subject. The obtained results suggest that interpersonal rejection can be effectively manipulated and studied in the laboratory without the use of any explicit derogation or overt hostility toward the target.

Public self-consciousness. The study found that individual differences in public self-consciousness had strong and consistent effects on reactions to an interpersonal rejection. After being shunned by a peer group, high publicly self-conscious women were less attracted to the group and were less likely to continue affiliating with that group than women low in public self-consciousness. Presumably, persons high in public self-consciousness were more aware of how they were seen by others. Thus, they were more sensitive to the shunning and were more disposed to avoid the people who ignored them.

It was assumed that private self-consciousness would have no effect on reactions to rejection. The focus of the experimental situation was on how subjects were perceived by others, that is, on their social self, and private, covert aspects of the self were considerably less salient. Covariance analyses confirmed that the role of private self-consciousness was negligible in this situation. Thus, the present study provides further evidence of the discriminant validity of the two self-consciousness dimensions (see also Scheier & Carver, 1977).

It is important to note that public self-consciousness had no effect on perceptions of the group's behavior. The "rejection group" was seen as equally unfriendly by both low and high self-conscious persons. Their different reactions were presumably a result of differing sensitivities to or differing interpretations of the group's behavior. That self-consciousness affects one's interpretation of an event is suggested by the finding that publicly self-conscious persons tended to see themselves as being largely responsible for the group's behavior. Both Duval and Wicklund (1973) and Taylor and Fiske (1975) postulate that attentional mechanisms are major determinants of causal attributions, that is, causes are of-

ten attributed to the most salient source of information, and salience is highly dependent on attention. Thus, the high publicly self-conscious person, because she or he directs attention to herself or himself (even while observing others), is likely to perceive a causal relationship between the self and the behavior of others. Events perceived as unrelated to the person have little impact on that person. However, if those same events are believed to be personally relevant, they should have a strong effect on behavior (Jones & Davis, 1965). The publicly self-conscious person presumably sees the rejection as being uniquely focused on or caused by her- or himself, and this self-blame for the aversive event may add to the negativity of the reaction (e.g., Abramson & Sackheim, 1977; Kuiper, 1978).

Acceptance

It may be argued that just as self-focused attention during an unpleasant interaction increases one's negative response, self-focused attention should also heighten the positivity of a positive interaction. Scheier and Carver (1977), for example, found that self-awareness increased responsivity to both positive and negative affective states in a nonsocial context. Although the acceptance condition of the present study may clearly be considered a pleasant encounter, reactions to this event were not altered by public self-consciousness. One possible explanation may be that persons high in public self-consciousness are especially sensitive to rejection but are not responsive to acceptance.

A related explanation for the failure of public self-consciousness to affect reactions to acceptance lies in the nature of the acceptance manipulation. Acceptance is neither an unusual nor an impactful occurrence, and it is unlikely that acceptance generates as much affect as rejection. As William James (1890) noted in his discussion of the social self, we all have the need to be noticed favorably, and there is "no more fiendish punishment" then to be ignored and have others act as if we were nonexistent. It may simply be that rejection and acceptance are not comparably balanced instances of positive and negative social interactions. Pilot observations and postexperimental interviews offer some support for this position. Rejected subjects displayed and reported a great deal of emotional discomfort, but very little emotion was shown by accepted subjects. In addition, accepted subjects were actively engaged in conversation: listening to and processing information, formulating and expressing opinions. To the extent that these behaviors were occurring, self-attention would be reduced and its effects mitigated (Duval & Wicklund, 1972). Rejected subjects, on the other hand, were much less involved in the ongoing interaction, and under these conditions, the effects of self-consciousness may have been considerably stronger.

Experiment 2

Experiment 2 was designed to provide a more unequivocal test of the effects of self-focused attention on *both* positive and negative interpersonal feedback. It was hypothesized that under conditions of increased self-attention, when persons become more aware of and concerned with self-evaluation, they also become more closely attuned to the self-relevant evaluations of others. Under these conditions, interpersonal feedback should be more salient than when attention is directed away from the self and self-evaluation is of little concern.[3] An attempt was made in this study to control (a) the involvement of subjects in the interaction and (b) the relative valences of the positive and negative feedback. Also, in order to enhance the plausibility and generalizability of a self-attention interpretation, self-awareness was experimentally manipulated in this study through the presence or absence of a mirror. Mirrors have been used extensively to induce self-awareness (e.g., Duval & Wicklund, 1973; Scheier et al., 1974), and there is now strong evidence that mirrors provide a valid means of increas-

[3] Theories of *deindividuation* lead to similar predictions. For example, Zimbardo (1969) argues that under conditions of deindividuation, a state in which one's sense of identity is lost, there is a decreased concern with self-evaluation or evaluation by others. Although it is tempting to argue that deindividuation represents the extreme low end of the self-awareness dimension, there is little research on the issue, and the question remains unresolved.

ing the occurrence of self-relevant thoughts (Carver & Scheier, 1978; Geller & Shaver, 1976).

Evaluative descriptions of the subject were provided in the context of an interview during which active participation by the subject was minimal. Subjects were presented with a generalized, impersonal interview that was either favorable or unfavorable.[4] Content was controlled so as to insure that positive and negative evaluations were of equal magnitude. Half the subjects were confronted with an unavoidable mirror image throughout the interview. This generated a 2 × 2 factorial design: favorable and unfavorable interview content crossed with mirror or no mirror. The major dependent variables were affective responses to the interview and the interviewer.

Method

Subjects

A total of 52 female undergraduates, all having siblings, were recruited from courses in introductory psychology. Four subjects were dropped from the experiment because they expressed suspicion during the postexperimental interview. The remaining 48 subjects were randomly assigned to the four experimental conditions: 10 each in the two positive feedback conditions and 14 in each of the two negative feedback conditions. (As explained below, these ns were unequal because the valence of the feedback could not be determined until after the experiment was over.)

Procedure

Subjects were brought into the experimental room and were told that they were going to take part in an interview. The purported purpose of the interview was to get the subject's "intuitive reactions to recent experimental findings concerning the effects of birth order on personality." These findings were described as either favorable or unfavorable to persons of the birth order of the subject. For example, if the interview was favorable to firstborns, then the subject would be in the positive feedback condition if she were a firstborn, but would be in the negative feedback condition if she were a later-born. Thus, the *same* interview content could serve as *either* pleasant or unpleasant feedback, with the subject's experimental condition determined by her birth order. The interview lasted about 10 min, during which time the female interviewer established brief eye contact with the subject only four times—once in the introduction, twice during the interview, and once at the conclusion. This was intended to minimize the induction of self-awareness through eye contact (e.g., Scheier et al., 1974). For half the subjects, there was a mirror directly behind the interviewer; for the other subjects, the mirror was turned around so that its reflective side faced the wall. Following the interview, subjects filled out a questionnaire evaluating the interviewer and the situation. Finally, the subject was debriefed.

Favorability manipulation. Essentially the same interview was given to all subjects, except that the terms *firstborn* and *later-born* were interchanged. After asking the subject some preliminary background information, the interviewer reviewed the "findings" on the relation of birth order to 11 different personality characteristics including warmth, assertiveness, independence, achievement, and intelligence. For half the subjects, firstborns were credited with the favorable aspects of these traits, and later-borns were given the unfavorable end. For the remaining subjects, this was reversed. Subjects were instructed not to reveal their birth-order position; thus, the experimenters were successfully blinded as to the subject's favorability condition.

Mirror manipulation. The mirror measured 3 feet × 2 feet (.91 m × .61 m) and was located on the wall directly behind and above the interviewer. The tilt of the mirror insured that the subject was exposed to her own image.

Dependent variables. At the conclusion of the interview, the subject filled out a questionnaire in another room, where a second experimenter was waiting. The questionnaire's ostensible purpose was to get information concerning the interviewer's strengths and weaknesses as seen by the subject. The questionnaire consisted of five 7-point scales concerning the interviewer and three 7-point scales about the interview. The major dependent variables were the subject's ratings of how pleasant and likable the interviewer was and how interesting and pleasant the interview was. Other scales dealt with the sincerity, competence, and poise of the interviewer and with how "personal" the situation was. In addition, subjects were asked to indicate on a 7-point scale how anxious they felt during the interview.

Results and Discussion

Affective Responses

The affective responses toward the interviewer and the interview were highly consistent (with correlations ranging from .52 to .73), and so they were combined into one overall affective rating (see Table 4). Again, as expected, positive feedback led to more

[4] The procedure and interview were originally developed by Ellsworth and Carlsmith (1968), and the reader is directed to that study for further details.

[5] Measures of attribution concerning the "cause" of the evaluative feedback were not considered relevant here because the feedback was presumably derived from "scientific findings" rather than from the principals in the experiment.

positive feelings then negative feedback, $F(1, 44) = 6.10$, $p < .02$, and there was no main effect for the mirror. The interaction was highly significant, $F(1, 44) = 7.73$, $p < .001$, indicating that the effects of the verbal evaluations were strongly influenced by the presence or absence of a mirror. Planned contrasts revealed that when the interview was critical, subjects responded more negatively in the presence of the mirror than in its absence, $t(26) = 2.98$, $p < .005$; following positive feedback, there was a nonsignificant tendency toward greater positive affect in the mirror condition.

Other Interview Measures

Concerning the ratings for the interviewer's competence, sincerity, and poise, and for how personal the situation was, there were no significant effects. From these results, it can be inferred that the interviewer's presentation was consistent across conditions, and the experimental manipulations had no effect on the subject's objective appraisal of the interviewer's capabilities. Finally, there were no significant differences between the ratings of firstborns and those of later-borns.

Anxiety

Subjects in the negative feedback group ($M = 3.0$) were more anxious than the positive feedback subjects ($M = 2.0$), $F(1, 44) = 6.40$, $p < .02$. The mirror by itself did not evoke anxiety, and the interaction was not significant.

Table 4
Mean Overall Affective Response Toward the Interview and Interviewer for Each Treatment Group of Experiment 2

Stimulus	Positive evaluation	Negative evaluation
No mirror	5.1	5.2
Mirror	5.6	4.1

Note. Ratings were on a 7-point scale on which 1 corresponded to a highly unfavorable response and 7 to a highly favorable one.

Eye Contact

The interviewer reported that subjects reciprocated over 92% of her gazes across all conditions. It could be argued that the mirror merely provided an easily available distraction to avoid a gaze-averting interview. However, these data suggest that the interviewer's eye contact was consistently met and cast serious doubt over any attempt to explain the effects of the mirror as due to its "distraction" qualities.

Discussion

It was hypothesized that evaluations from others would have a greater effect on subjects in the presence of a mirror than in its absence. These predictions were partially confirmed: The mirror substantially enhanced negative reactions to negative interpersonal feedback; the effect for positive feedback was in the expected direction but was not significant. Overall, the results suggest that self-attention intensifies the process of self-evaluation, and when self-awareness is low, the importance of self-relevant information from others is reduced.

It may be argued that the mere absence of a mirror is not sufficient reason to assume a low state of self-awareness. But, as in the present experiment, if the mirror's absence is combined not only with an interviewer who establishes a minimal amount of eye contact but also with a highly impersonal interview about birth order (in general, not specifically the subject's own), then there may be sufficient justification to argue for considerably diminished self-awareness in the no-mirror condition.

General Discussion

Empirical Findings

It has been widely assumed by self-consciousness theorists (e.g., Argyle, 1969; Goffman, 1959; James, 1890) that when attention is directed toward the self, there is an increased concern with how one is perceived by others; and when self-attention is low, feedback from others is of little importance.

The present research provides confirmation of these hypotheses. The results of both studies together demonstrate that when persons become more aware of the self during social interactions, because of either chronic dispositions toward self-consciousness or the reflection of their images in a mirror, there is an increased responsiveness to the evaluations of others (especially in the case of unpleasant feedback).

Although the present research has been interpreted in terms of self-attention processes, it may be argued that both public self-consciousness and the mirror produce an increase in *arousal* and a facilitation of dominant responses (e.g., Liebling, Seiling, & Shaver, 1974). In the present context, dislike and liking could be construed as the dominant responses to disparaging and complimentary feedback, respectively. This alternative explanation of the results is weakened by several considerations. The mirror in the second study had no consistent effect on subjects' self-reported anxiety. The lack of an association between the mirror and arousal is corroborated by physiological research showing that mirrors do not increase palmar sweating (Paulus, Annis, & Risner, Note 1). In the first study, covariance analyses established that the effects of public self-consciousness were independent of the effects of social anxiety. Thus, although high publicly self-conscious subjects may be more anxious in the presence of others than subjects low in public self-consciousness, this anxiety apparently does not account for their reactions to rejection. In addition, Carver and Glass (1976) found public self-consciousness to be uncorrelated with test anxiety and only weakly correlated with emotionality. There appears to be little evidence that arousal played a major role in either study. On the other hand, the fact that both a stable self-consciousness attribute (in Experiment 1) and a self-reflective stimulus (in Experiment 2) produced similar results lends support to an attentional explanation.

Direction of Causality

The convergence between the findings of the two studies also allows a question of causal interpretation to be resolved. Since public self-consciousness in Experiment 1 was a nonmanipulated individual difference, its causal relationship to reactions to rejection cannot be clearly established. It had been assumed that being aware of oneself as an object of attention to others causes rejection to be especially painful. However, it may be that vulnerability to rejection both causes persons to become chronically self-conscious and increases their sensitivity to rejection.[4]

Although this latter interpretation is a plausible account of the results of the first study and cannot be ruled out completely, it seems unlikely that a specific concern, such as fear of rejection, would induce a generalized state of public self-consciousness. Moreover, fear of rejection should be reflected in a measure of social anxiety, and as already indicated, there is only a modest correlation between social anxiety and public self-consciousness. Most importantly, the results of Experiment 2, in which self-attention was experimentally induced, clearly demonstrate that heightened sensitivity to social evaluation is a function of self-attention. Given the similarities in paradigm for the two studies, it seems reasonable to infer that an analogous causal sequence was operating in Experiment 1.

Positive and Negative Social Interactions

Experiment 1 found that publicly self-conscious women were highly vulnerable to rejection but were not responsive to acceptance. However, because it was difficult to determine the relative negativity of rejection compared to the positivity of acceptance in that study, a second experiment was conducted in which the valences of positive and negative social interactions were more comparable. Again, the effects of self-attention were stronger for unfavorable feedback than for favorable feedback. Although further research is warranted, the consistency of the present findings suggests a negativity bias (see Kanouse & Hanson, 1972) such that concern over evaluations is particularly focused on the possibility of negative rather than positive feedback. It

[4] The author is indebted to an anonymous reviewer who raised this argument.

would then follow that the salience of negative events such as rejection or criticism is heightened more by self-awareness than the salience of positive events such as acceptance or praise.

Self-Awareness Theory

Self-awareness has been construed primarily as a process that regulates the direction and intensity of thoughts, feelings, and actions (Duval & Wicklund, 1972). Much of the research in this area has been interested either in the relationship between behavior and standards of behavior (e.g., Carver, 1974; Scheier et al., 1974) or in the effects of self-focused attention on internal states (e.g., Scheier & Carver, 1977) and cognitive phenomena (e.g., Carver & Scheier, 1978). In the context of this previous research, it has been assumed that self-focusing stimuli such as mirrors direct attention toward covert, internal aspects of the self. Similarly, interest in personality dimensions of self-consciousness has concentrated primarily on the private component (e.g., Scheier, 1976).

The study of self-awareness, then, seems to have been largely concerned with what James (1890) called the "spiritual" self, which refers to our inner being, our cognitive faculties, our emotional states, and our behavioral tendencies. But the self involves many facets, and a particularly important constituent is the "social" self (James, 1890), which is concerned with the recognition or regard we get from others. The present research suggests that when we attend to ourselves in social situations, it is the social self that is focused on; that is, we become more aware of ourselves as objects of attention to others. In this respect, it has been shown that public self-consciousness (awareness of ourselves as social objects), rather than private self-consciousness (awareness of our internal selves), is the crucial determinant of how much the evaluations of others affect us. In addition, the parallel between the effects of public self-consciousness and the mirror manipulation suggests that in social situations, mirrors direct attention toward the public, external aspect of the self. Thus, the consequences of self-attention are not limited to a greater awareness of our own standards, emotions, and cognitions; self-attention also affects our awareness of the self-relevant actions, thoughts, and feelings of others. Self-awareness theory needs to acknowledge the existence of both the private, internal self and the public, social self if it is to develop a fuller understanding of our unique ability to be conscious of ourselves.

Conclusion

The present findings indicate that self-attention is an important mediator of social behavior. By raising or lowering attention to oneself, one can heighten or diminish the effect of others' evaluations, perhaps through the facilitation of selective attention processes (Duval & Wicklund, 1972). Indeed, our own personal exerience would suggest that the reduction of self-attention through, for example, avoiding eye contact (Fenigstein, Note 2) or engaging in random physical activity (Duval & Wicklund, 1973) may be an effective strategy for warding off the impact of criticism, derogation, or embarrassment. Further research confirming these inferences would suggest that the control and modification of self-attention may have implications for the way in which persons deal with the social feedback of everyday life.

Multidimensional Reaction to Therapeutic Touch in a Hospital Setting

Sheryle J. Whitcher and Jeffrey D. Fisher
University of Connecticut

A field experiment focused on some implications of interpersonal touch not explored in earlier research. Conceptually, the research included measuring the effects of touch over a relatively long time frame, for a broad range of response dimensions, and in a nonreactive setting characterized by dependency. On an applied level, the research studied the value of touch as a concomitant of nurse–patient interactions. Specifically, a 2 (touch vs. no touch) × 2 (male vs. female) between-subjects design assessed the effects of nurses touching patients, during preoperative teaching, on patient affective, evaluative, behavioral, and physiological responses. Results indicated that female subjects in the touch condition experienced more favorable affective, behavioral, and physiological reactions than a no-touch control group. In contrast, males in the touch condition reacted more negatively than control subjects on these dimensions.

Background

The various modes of nonverbal communication (e.g., proxemics, eye contact) have received increased attention from social psychologists in recent years. There have been several theoretical (e.g., Argyle & Dean, 1965; Patterson, 1976) and numerous empirical (e.g., Buck, Miller, & Caul, 1974) attempts to understand the way nonverbal messages are interpreted and to predict the quality of subsequent reactions.

Surprisingly, although touch is considered by many to be the most powerful of the nonverbal modalities, it has traditionally received the least research attention (Duncan, 1969). Further, what data are available on tactile stimulation have generally focused on the responses of animals and human infants to touch. Within the animal literature, studies have revealed that early tactile contact can influence later emotional and physiological behavior (Denenberg, 1963; Harlow, 1971; Levine, 1960). With human infants, the classic work of Spitz (1946) and more recent research by Montagu (1971) highlight the importance of touch as a stimulus essential for normal intellectual, emotional, and social development.

Only in the last few years have researchers begun to explore the parameters of touch with human adults. Further, the limited work with this population suggests that the effects of touch may be either positive or negative. For example, in research demonstrating positive consequences, Kleinke (1977) reported that touch led to greater compliance than in a control group, and Fisher, Rytting, and Heslin (1976) observed that females who were touched experienced more positive affective and evaluative reactions than no-touch controls. In research suggesting negative effects, Walker (1971) reported that communication by means of touch made subjects feel anxious and uncomfortable, and Henley (1973) observed that touch may be perceived as ex-

This research was supported in part by Research Grant 5.171-000-22-0215-35-335 from the University of Connecticut Research Foundation to Jeffrey D. Fisher. Portions of this article were presented at the meeting of the Psychonomic Society, Washington, D.C., November 1977. ploitative and/or as highlighting the lower status of the recipient. Finally, it has been shown that the same touch may be experienced positively by one sex and negatively by the other (Fisher et al., 1976; Nguyen, Heslin, & Nguyen, 1975).

A review of past research with adult populations suggests that whether touch is experienced positively or negatively depends on the meaning and evaluation inferred by the recipient (Fisher et al., 1976). Clearly, touching a person can mean many things, for example, a desire for intimacy, sexual attraction, or dominance. Further, any of these messages could be expected to elicit negative reactions if it oversteps the boundaries a person has defined as appropriate. In line with these observations, and supported by conceptual work on nonverbal communication (Altman, 1975; Argyle & Dean, 1965; Patterson, 1976), Fisher et al. (1976) suggested that a touch will be experienced as positive to the extent that it (a) is appropriate to the situation, (b) does not impose a greater level of intimacy than the recipient desires, or (c) does not communicate a negative message (e.g., is not perceived as condescending). These assertions have also been supported in empirical work (e.g., Hall, 1966; Henley, 1973; Nguyen et al., 1975).

Problems With the Extant Literature on Touch

Although the present literature on touch in human adults affords some organizing notions for predicting responses and suggests that reactions may vary widely, it is limited in important ways. For example, the range of situations examined has been decidedly narrow (e.g., touch has rarely been studied in situations characterized by dependency, anger, or sexual intimacy; Henley, 1977). Also, very few studies have been conducted in a nonreactive context (Fisher et al., 1976), which is a serious limitation, since touch is associated with strong socialization-related prohibitions (Heslin, Note 1). In addition, past research has measured only reactions that occur very soon after tactile stimulation; the longer-term consequences of touch have yet to be explored. Further, the responses assessed have generally been limited to the affective and evaluative domains; behavioral and physiological reactions to touch have been measured infrequently, and no research has provided a simultaneous assessment of all four response dimensions. Finally, most studies on the effects of touch have been empirical demonstrations. Little research has been conducted either to test a particular conceptual perspective or in a context where findings could have direct applied significance.

The Present Experiment and its Implications

The present experiment was designed to yield initial data pertinent to some of the weakness of past research described above. Specifically, the study explored the effects of nurse–patient touch in a hospital setting. On a conceptual level, this research contributes to the extant literature in the following ways. First, nurse–patient interactions are highly characterized by dependency (Barnett, 1972), a context variable ignored in past research on touch (Henley, 1977). In addition, the effects of touch were simultaneously assessed on affective, evaluative, behavioral, and physiological dimensions, and over a relatively long period of time. Finally, the nature of the touch stimulus and of the dependent measures rendered the study relatively unobtrusive, so that it would be affected less by problems associated with reactivity.

In addition to its conceptual implications, the experimental study of touch in a hospital setting may have practical value. Although no past research on nurse–patient interaction has directly measured the applied consequences of tactile stimulation, the potential of touch is suggested by work in related areas. Specifically, it has been found that hospitalization is frequently an anxiety-laden, depersonalized situation (Barnett, 1972), that appropriate supportive care (of which touch may constitute an element) leads to reduced anxiety (Johnson & Leventhal, 1974), and, most importantly, that the level of patient anxiety may be related to postoperative recovery (Johnson, Leventhal, & Dabbs, 197

Hence, by addressing the effects of touch in the present setting, this study may disclose some initial answers to an important applied problem.

Predicting the Effects of Touch in a Hospital Context

In predicting the effects of touch in a context characterized by dependency, some important factors should be taken into account. Clearly, in such a setting touch may convey a mixture of positive (e.g., caring) and negative (e.g., power, dominance) elements (Henley, 1977; Heslin, Note 1). This interpretive ambiguity is exacerbated, because in a physical sense, touches that express negative aspects of dependency (e.g., inferiority) and those that express positive aspects of caring and concern are quite similar (Henley, 1977; Heslin, Note 1). Thus, it is not surprising that competing rationales exist for predicting which of these two messages will be most salient.

One prediction stems from research on sex differences in socialization. Specifically, it is assumed that males are socialized to be more uncomfortable with dependency than females (Hoffman, 1972; Maccoby, 1966; Stein & Bailey, 1973). Further, since touches signaling dependency and those expressing caring may be physically similar, it is believed that socialization may importantly affect their interpretation. Thus, females may interpret nurse–patient touch as a primarily positive message of caring and warmth, which is situationally appropriate and of a reasonable level of intimacy (cf. Fisher et al., 1976). On the other hand, males may react negatively, because they interpret the nurse's touch as conveying a message of relative inferiority and dependency, which is neither situationally appropriate nor of a comfortable level of intimacy. In effect, it is suggested that touch in a dependency context is more sex role-appropriate for females than for males and should therefore lead to more positive female than male responses across measurement indexes (e.g., affect, evaluation). While sex role-inappropriate touch has been shown to lead to negative effects in other contexts (e.g., romantic encounters; Nguyen et al., 1975), it has not yet been explored in dependency situations.

An opposing prediction centers on the special status that may be accorded to dependency that results from illness. Specifically, when one is a patient, being dependent may be socially acceptable for both sexes. In line with this interpretation, it would be expected that both males and females would interpret nurse–patient touch as an expression of caring that is situationally appropriate and of a reasonable level of intimacy (cf. Fisher et al., 1976). If this hypothesis were supported, the positive reaction of males and females to touch should generalize across the various response dimensions.

Method

Subjects

Subjects were patients at a major university hospital complex. Forty-eight individuals (19 males, 29 females) who entered the hospital for elective surgery participated in the study; anonymity was maintained through the use of code numbers. The prerequisites for inclusion were (a) an adequate reading and speaking knowledge of English, (b) signing a document upon admission to the hospital that permitted participation in research,[1] (c) assignment to the seventh floor of the hospital, and (d) assignment to a primary nurse who had agreed to participate in the study.[2] All individuals who met these criteria were included in the experiment.

Design

A 2 (touch vs. no touch) × 2 (male vs. female) between-subjects design was employed, in which patients were randomly assigned to conditions. For ethical reasons, and to permit a comparison with "routine procedures," individuals in control groups were not deprived of any aspect of normal hospital care and were exposed to customary professional/functional tactile contact with nurses. In experi-

---

[1] The number of patients who refused to sign the informed-consent document averaged 10%, with no differences between the experimental cells.

[2] All nursing personnel scheduled to work on the seventh floor volunteered to take part in the study and were blind to the experimental hypotheses. Further, it should be noted that primary nursing care, a system in which a patient is assigned to one nurse who coordinates care throughout the hospital stay, is used at the facility where the study was run.

mental conditions, the nurses administered an additional touch manipulation (described in detail below) during the preoperative teaching session. The same nurses conducted preoperative instruction with patients in the experimental and control groups.

Experimental Procedures

If a patient met the prerequisites for participation, the floor clerk attached a specially prepared "work sheet" to his or her medical chart when it arrived at the seventh floor. The work sheet specified the patient's treatment condition and had been randomly sequenced by the experimenter prior to the beginning of the experiment. When the nurse examined the patient's chart, the work sheet informed her if the patient was participating in the study and what condition he or she was in.

The experimental manipulation took place shortly after admission. Initially, the nurse closed a curtain that separated the patient from any other individuals in the room. Next, she touched the patient's hand for a few seconds while introducing herself and explaining that she was going to inform the patient about his or her surgery. Toward the end of the teaching session, the nurse gave the patient a booklet that further detailed the procedures for surgery, to be read at his or her leisure. At that time the nurse put one hand on the patient's arm and maintained this touch for approximately 1 minute, while she and the patient examined the booklet.[3] Patients in the control condition experienced the same interaction without physical contact. Subsequent to this, in both the experimental and control groups, the nurse extended her hand in a gesture suggesting contact and noted the patient's response as an unobtrusive measure of the subject's desire to reciprocate contact.

Upon completing the teaching session, the primary nurse left the room. Several hours later the patient was approached by a male experimenter, blind to experimental hypotheses, who explained that the university was conducting a study of patient reactions to hospitalization. The experimenter requested that the patient fill out a questionnaire, emphasizing that all responses were anonymous and confidential. The patient was asked to seal the completed form in an envelope, which was later collected by the experimenter.

Dependent Measures

The dependent measures that were used to assess the effects of touch represented a set of affective, evaluative, behavioral, and physiological indexes expected to discriminate between patients who react favorably and those who react unfavorably to the hospital experience.

Measure of Affect

The measure of affect was contained in the questionnaire administered by the experimenter. It consisted of three items with intercorrelations above .40 that assessed the nature of the patient's feelings concerning hospitalization and surgery. Specifically, the items measured how anxious patients felt about having to undergo surgery, how unpleasant it was for them to be in the hospital, and how worried they were concerning the possibility of postoperative complications. Each item was presented as a 7-point semantic differential rating scale, ranging from "not at all" to "extremely."

Evaluative Measures

The evaluative measures were also contained in the questionnaire administered by the experimenter. These consisted of a measure of satisfaction with preoperative instruction and one reflecting attraction toward the nurse.

Measure of satisfaction with preoperative instruction. This index consisted of two items, which asked patients how satisfied they were with the information they received concerning surgery and how satisfied they were with the nursing care provided up to that point. The items showed an intercorrelation of .36 and were arranged as 7-point semantic differential scales with endpoints of "not at all" and "extremely."

Measure of attraction. Three items comprised a measure of the degree of patient liking for the nurse. Specifically, they asked patients to indicate how warm they perceived the nurse to be, how interested they felt the nurse was in their questions and feelings about surgery, and how friendly they felt toward the nurse. The items showed intercorrelations above .50, and each was presented as a 7-point semantic differential scale with endpoints of "not at all" and "extremely."

Behavioral Measures

Two unobtrusive measures were included that assessed responses made by subjects during their hospital stay.

Measure of preoperative material read. It was assumed that touch might lead to differential patient reading of the booklet left by the nurse during preoperative teaching. Therefore, a 4-point Likert-type scale assessed how much of the booklet the patient had read. This measure ranged from "none at all" to "the entire booklet thoroughly."

---

[3] Prior to running subjects, the researchers observed the setting and the procedure in which the touch stimulus was to be introduced. This was done to verify that the touch manipulation could be performed naturally and could fit comfortably in the preoperative instruction. Further, the researchers trained the staff in the execution of the touch. All nurses role played the manipulation with each other before the experiment began to insure that it would be administered in a uniform fashion. In addition, they were provided with a typewritten set of instructions, which they reviewed periodically.

Measure of reciprocation of touch. At the end of the preoperative instruction, the nurse extended her hand in a gesture that allowed for reciprocal intimacy and then observed the patient's reaction. The response was coded in terms of whether the patient (a) grasped or touched the nurse's hand, (b) reached toward but did not touch the nurse's hand, (c) looked at but did not reach toward the nurse's hand, or (d) ignored the nurse's gesture.

Physiological Measures

The physiological data recorded for patients included measures taken directly after surgery while the patient was in the recovery room and periodic vital signs readings collected by the staff during the first several days of hospitalization. Specifically, the recovery room data consisted of five repeated measures of patient pulse and systolic and diastolic blood pressure, recorded at 15-minute intervals. The periodic vital signs data consisted of seven repeated measures of pulse, temperature, and systolic and diastolic blood pressure, collected approximately every 4 hours after the preoperative teaching. Past research has shown that these indexes can be considered to discriminate between anxious and nonanxious patients (e.g., Martin, 1961). All readings of blood pressure were recorded by a Baum portable mercury-meter sphygmomanometer with a branchial artery cuff. Measures of heart rate were assessed by a radial pulse, and temperature data were recorded with a standard mercury thermometer.[4]

Results

Equivalence of Groups

Preliminary 2 (touch vs. no touch) × 2 (male vs. female) analyses of variance (ANOVAs) and chi-square tests were run to insure that randomization had resulted in equivalence of patients in all cells. Since the ANOVAs revealed no differences between groups in terms of physiological indexes or age at hospital entry ($Fs < 1$), and the chi-square tests indicated no differences in type (e.g., orthopedic, eye, thoracic) or severity (major vs. minor) of surgery ($\chi^2 < 1$), each of the groups was assumed to be equivalent. Thus, the dependent variables were subject to further analysis.

Measure of Affect

A 2 (touch vs. no touch) × 2 (male vs. female) multivariate ANOVA was performed on the three questionnaire items pertaining to affect concerning surgery.[5] This procedure revealed a significant main effect for touch, $\lambda(1, 3) = 3.09$, $p < .037$, which was qualified by a significant Touch × Sex interaction, $\lambda(1, 3) = 4.84$, $p < .006$. Parallel univariate analyses run on the three affect items indicated a similar pattern of findings.

Specifically, the univariate analyses revealed a significant main effect for touch on the item reflecting worry about complications, $F(1, 43) = 9.27$, $p < .004$, and a marginally significant main effect for touch on the item that measured unpleasantness of hospitalization, $F(1, 43) = 2.82$, $p < .10$. These findings indicated that patients who were touched during preoperative instruction experienced more positive reactions than individuals not touched. Further, a significant univariate Touch × Sex interaction was observed for ratings of anxiety concerning surgery, $F(1, 43) = 15.01$, $p < .001$, and trends toward significant Touch × Sex interactions were observed for the measures of unpleasantness of hospitalization ($p < .13$) and worry about complications ($p < .16$); see Table 1. For the measure of anxiety concerning surgery, Newman-Keuls comparisons indicated that females who were touched reported less anxiety than control females ($p < .05$), whereas males in the touch condition reported more anxiety than control males ($p < .05$). Also, females were more anxious than males in control conditions ($p < .05$), whereas males were more anxious than females in touch conditions ($p < .05$). The overall pattern of the nonsignificant interactions paralleled that observed for the measure of anxiety concerning surgery.

---

[4] All experimental procedures were approved by the hospital ethics committee composed of doctors, lay people, and clergy.

[5] F_{max} tests indicated that homogeneity of variance was maintained for all of the dependent measures. Since there were minor discrepancies in the n in various cells, a least squares ANOVA was used (cf. Overall & Spiegel, 1969; Winer, 1971). Finally, the Wilks's Lambda criterion (Finn, 1974) was used as a significance criterion for all the multivariate tests.

Table 1
Cell Means for Touch × Sex Interactions

Measure	Touch		No touch	
	Male	Female	Male	Female
Anxiety over surgery	6.2$_a$	3.8$_b$	3.9$_b$	5.9$_a$
Unpleasantness of hospitalization	3.2$_a$	3.5$_a$	3.0$_a$	5.3$_a$
Worry concerning complications	3.0$_a$	2.9$_a$	3.6$_{a,b}$	5.1$_b$
Recovery room systolic pressure	144.6$_a$	121.8$_a$	126.9$_a$	135.0$_a$
Recovery room diastolic pressure	96.2$_a$	78.3$_a$	82.4$_a$	83.1$_a$

Note. Means with common subscripts do not differ at the .05 level, as indicated by the Newman–Keuls procedure. For the measures of anxiety over surgery, unpleasantness of hospitalization, and worry about complications, scores can range from 1 (low) to 7 (high).

Evaluative Measures

Measure of Satisfaction With Preoperative Instruction

A 2 × 2 multivariate ANOVA and parallel univariate ANOVAs performed on the two questionnaire items assessing patient satisfaction with preoperative teaching were not significant. However, responses on these measures indicated a ceiling effect, that is, patients in all conditions felt extremely satisfied with the information and nursing care they received.

Measure of Attraction

A 2 × 2 multivariate ANOVA and parallel univariate ANOVAs performed on the three questionnaire items that assessed patient liking for the nurse revealed no significant effects. However, when the data for males and females were analyzed separately, some suggestive findings emerged. For females, the multivariate ANOVA indicated a trend toward a main effect for touch, $\lambda(1, 3) = 1.64$, $p < .20$. This finding was paralleled by a univariate effect for touch on the item measuring perceived nurse interest, $F(1, 26) = 5.10$, $p < .03$, which suggests that females perceived nurses who touched to be more interested in them than nurses who did not touch. For the measures of perceived nurse warmth and friendliness, the separate male–female univariate analyses revealed no significant effects; however, responses on these items indicated a ceiling effect.

Behavioral Measures

Measure of Preoperative Material Read

Patient reading of the preoperative teaching booklet was measured on a 4-point scale. The overall 2 × 4 chi-square analysis was significant, $\chi^2(3) = 9.10$, $p < .03$, and suggested that patients in the touch condition read more of the booklet than controls. Separate 2 × 4 chi-square tests revealed that for females, the effect of touch paralleled the overall chi-square analysis, $\chi^2(3) = 10.63$, $p < .01$. However, for males the separate analysis was nonsignificant, $\chi^2(3) = 1.78$, $p < .5$, indicating that it was the female data that were primarily responsible for the overall effect.

Measure of Reciprocation of Touch

Patient responses to the nurse's outstretched hand were coded on a 4-point scale reflecting the subject's desire for reciprocal intimacy. The overall 2 × 4 chi-square analysis was marginally significant, with patients in the touch condition more frequently reaching out and touching the nurse's hand relative to control patients, $\chi^2(3) = 6.97$, $p < .07$. Separate 2 × 4 chi-squares for males and females revealed that while the pattern approached significance for females, $\chi^2(3) = 7.39$, $p < .06$, it was not significant for males ($\chi^2 < 1$). Here again, it was the female response that determined the overall effect.

Physiological Measures

Recovery Room Measures

A 2 (touch vs. no touch) × 2 (male vs. female subject) × 5 (time) ANOVA was performed for each of the physiological measures taken in the recovery room.

Systolic blood pressure. The ANOVA performed on the recovery room index of systolic blood pressure revealed a significant Touch × Sex interaction, $F(1, 31) = 4.15$, $p < .05$ (see Table 1). The pattern of the means indicates that at all five measurement intervals, touch females tended to have lower systolic pressure than control females, whereas touch males tended to have higher readings than male controls. However, Newman-Keuls analyses revealed that none of these differences were significant. The overall ANOVA further revealed a significant effect for time, $F(1, 128) = 2.85$, $p < .03$, which indicated that patients in both conditions demonstrated a significant decline in systolic pressure over the period of measurement.

Diastolic blood pressure. The ANOVA performed on the five measures of diastolic blood pressure showed a significant Touch × Time interaction, $F(1, 128) = 2.47$, $p < .05$, as well as a marginally significant Touch × Sex interaction, $F(1, 31) = 3.26$, $p < .08$ (see Table 1). Taken together, the interactions suggest that touch males tended to increase in diastolic blood pressure relative to control males over the five intervals. In contrast, touch females tended to decrease in diastolic pressure over time relative to control females. However, Newman-Keuls comparisons of the means did not reach a conventional level of significance for either interaction.

Pulse. The repeated measures ANOVA on the five pulse readings indicated that only the effect for time was significant, $F(1, 124) = 4.51$, $p < .003$, with patients demonstrating a decrease in pulse over the period of measurement.

Periodic Vital Signs Measures

In addition to the physiological data collected in the recovery room, periodic measures of pulse, temperature, and systolic and diastolic blood pressure were recorded for patients approximately every 4 hours after preoperative teaching. A 2 (touch vs. no touch) × 2 (male vs. female subject) × 7 (time intervals following preoperative teaching) ANOVA was performed on these measures.

Systolic blood pressure. The ANOVA on the periodic index of systolic pressure revealed a significant effect for sex of subject, $F(1, 30) = 13.46$, $p < .002$, with males demonstrating higher systolic pressure than females. Although the analysis failed to indicate a main effect for touch ($p < .26$), the direction of cell means suggested that patients in the touch condition ($M = 122.73$) tended to have lower systolic pressure over the seven measurement intervals than controls ($M = 127.37$).

Diastolic blood pressure. The ANOVA on the periodic diastolic blood pressure readings revealed a significant main effect for sex of subject, $F(1, 30) = 14.25$, $p < .001$, with males demonstrating higher diastolic pressure at all measurement intervals than females. The data further indicated a trend toward significance for the effect of touch, $F(1, 30) = 2.40$, $p < .13$, with patients in the touch condition ($M = 76.03$) tending to have lower diastolic pressure over the seven measures than controls ($M = 86.38$).

Pulse. The repeated measures ANOVA performed on the seven pulse readings revealed no significant effects ($Fs < 1$).

Temperature. The repeated measures ANOVA performed on the periodic vital signs temperature data revealed a significant effect for time, $F(1, 30) = 6.03$, $p < .001$, with patients showing an increase in temperature over the seven measurement intervals. This main effect was qualified by a significant Sex × Time interaction, $F(1, 186) = 2.26$, $p < .04$, which indicated that males' temperatures tended to increase at a more rapid rate than females'.

Discussion

In an attempt to provide some conceptual and applied data not available from earlier work, the present study explored the effects of touch in a hospital setting. The findings

on a variety of measures suggested that in this context, touch led to positive effects primarily for females. Specifically, on affective dimensions touch precipitated positive reactions for females, whereas the reverse was true for males. Further, the behavioral data indicated that touch led to reciprocal touching and to more extensive reading of the preoperative material for female but not for male subjects. Finally, several physiological indexes also tended to show this pattern of positive reactions only for females.

Evaluation of the Support for the Sex Difference Hypothesis

While there was a degree of inconsistency across the various dependent measures, the overall pattern of results supports the sex difference hypothesis, which predicts that when dependency cues are pervasive, males and females will react differently to touch. The rationale for this hypothesis is that males are socialized to be relatively uncomfortable with dependency (Hoffman, 1972; Maccoby, 1966; Stein & Bailey, 1973) and thus experience nurse–patient touch as a threatening gesture communicating inferiority and asserting dominance, which leads to negative reactions. Conversely, females are socialized to be relatively affiliative and comfortable with dependency (Hoffman, 1972; Maccoby, 1966; Stein & Bailey, 1973) and thus experience nurse–patient touch as a supportive gesture of caring and warmth, which leads to favorable reactions. Our support for the sex difference hypothesis complements earlier research on tactile stimulation. In contexts other than dependency, it has been found that when touch conveys a sex role-inappropriate message, negative effects occur (Nguyen et al., 1975; Heslin & Boss, Note 2).

Although the present data were explained in terms of the sex difference hypothesis detailed above, several other possibilities are tenable. One centers on females' richer and more varied tactile history. Specifically, females are touched more often by a variety of others (mother, father, same/opposite-sex friends) than males (Jourard, 1966; Jourard & Rubin, 1968), and in other nonverbal modalities (e.g., personal space) they display more permeable boundaries. Further, females probably have more exposure to tactile stimulation in medical contexts than males (e.g., yearly gynecological exams, giving birth). Hence, touch during preoperative teaching may have been reassuring for females but disruptive for males in part because males have less experience with touch in general and, more particularly, in medical contexts.

A second possibility stems from the fact that female patients interacted with a same-sex other, whereas males interacted with an opposite-sex individual. Since there was no way to separate out the possible confounding influence of sex of toucher from the effects of touch in the present setting, it is possible that being touched during preoperative teaching was a qualitatively different experience for males and females. For example, males could be more likely than females to interpret the present touch as sexual in nature. However, past research tends to argue against this possibility. Specifically, a study by Nguyen et al. (1975) indicates that touches to the hand and/or shoulder, whether applied by a same- or an opposite-sex other, are interpreted as nonsexual in nature. Further, an earlier field experiment that varied sex of toucher and employed a similar touch manipulation found no differential effects for sex of toucher (Fisher et al., 1976). Nevertheless, it is not possible to rule out the above explanation solely on the basis of this study.

Consistency of the Data Across Dependent Measures

While the present findings generally showed a consistent pattern of effects for the affective and behavioral measures, the physiological measures were less consistent. For example, the measures taken in the recovery room indicated that touch females had lower systolic and diastolic blood pressure than controls, whereas similar measures taken in the patient's room showed only a trend toward a effect for touch. Also, indexes of pulse and temperature did not discriminate between experimental and control conditions. Inter

estingly, on some of these measures sizable mean differences were obtained, yet effects were not significant. If the high degree of variability associated with physiological measurement is taken into account (e.g., Martin, 1961), these nonsignificant patterns become more impressive. Further, it should be noted that where sources of variability were minimized (i.e., in the recovery room), stronger effects were observed than under less controlled conditions (i.e., in the patient's room).

Although the affective, behavioral, and physiological measures were generally sensitive to the effects of touch, the evaluative items were not. We think that this result can be explained in terms of a ceiling effect, since the means show almost no differences and indicate that all patients felt very positively toward the nurse and were extremely satisfied with their preoperative teaching. Considering the very high level of health care at the hospital where the present study was run, a ceiling effect on these indexes should not have been unexpected. However, it would not be unreasonable to expect stronger effects on evaluative measures in settings where health care is much less personalized (e.g., emergency rooms).

Conceptual Implications

Moving to conceptual implications, the present data may be seen as adding to the extant literature. For example, past research tended to look at single rather than multiple responses to tactile stimulation. Based on this study, it appears that touch may have consequences for affective state, behavior, and physiological reactions and that these response modalities may be related (i.e., parallel effects may occur along all three dimensions). Further, the data provide a first look at some long-term consequences of touch, suggesting that it may have powerful multidimensional effects over time, in addition to the short-term effects demonstrated in earlier research (e.g., Fisher et al., 1976). It should be noted, however, that touch in the present study occurred in a context where it was particularly salient and meaningful. While touch in other situations of this type might be expected to have long-term consequences, the effects of incidental tactile stimulation (cf. Fisher et al., 1976) or touch that is commonplace or role defined should be relatively short-term.

It is of further conceptual interest that the present findings are in accord with Patterson's (1976) arousal model of interpersonal intimacy and can be interpreted in terms of that formulation. According to Patterson, changes in intimacy produce arousal change, which may be a signal to evaluate and interpret the environment. The change in arousal may be labeled as positive or negative, depending on the context in which it occurs (e.g., socialization-related beliefs concerning touch and dependency). To the extent that a positive label is engendered, it is assumed that favorable reactions (e.g., positive affect, reciprocal intimacy) will occur. In the present situation for females, contextual factors may have permitted a positive label for decreased arousal, which resulted in favorable affective, physiological, and behavioral reactions. For males, the context may have produced a negative labeling of increased arousal, which resulted in unfavorable responses on these dimensions. It is suggested that the fit of Patterson's model to the present data indicates that it may be useful as an interpretive framework for past research on touch and as a predictive framework for future work.

Practical Implications

Finally, the results of this study may have practical implications for patient care. Earlier research (e.g., Johnson et al., 1971) found that various conditions that facilitate low preoperative anxiety improve patient recovery. In the present study, touch for females resulted in lower anxiety and more positive behavior preoperatively, and these results were associated with more favorable postoperative physiological responses. This finding suggests that touch during preoperative teaching is a form of communication that may be beneficial to the well-being of certain patients. Clearly, however, the negative reactions of males in the present context prohibit any unqualified statements concerning the practi-

cal implications of the data. Before application will be possible, future research must assess the consequences of touch across a variety of medical settings and individual difference variables, in order to very precisely delineate the domain in which touch has beneficial effects.

Conclusions

In conclusion, touch in a hospital setting tended to elicit positive reactions in females and more negative reactions in males. It was suggested, based on these findings, that male and female subjects attributed differential meaning to touch in a dependency context. Further, the findings demonstrated that touch may have long-term effects, that reactions to touch may be related across various response dimensions, and that tactile stimulation in a hospital setting may sometimes be of therapeutic value.

Effects of Message Repetition and Position on Cognitive Response, Recall, and Persuasion

John T. Cacioppo
University of Notre Dame

Richard E. Petty
University of Missouri—Columbia

Although the mere exposure effect has been researched widely, surprisingly little is known about the attitudinal and cognitive effects of message repetition. It was hypothesized that the sequence of topic-relevant thoughts generated in response to a (repeated) persuasive message would parallel attitude change. To test this prediction, two experiments were conducted. In Experiment 1, individuals heard a communication either zero (control), one, three, or five times in succession, rated their agreement with the advocated position, and listed the message arguments they could recall. In Experiment 2, individuals heard a communication either one, three, or five times, rated their agreement, listed their thoughts, and listed the message arguments they could recall. In both experiments, agreement first increased, then decreased as exposure frequency increased (regardless of the position advocated), but agreement was unrelated to the recall of the message arguments. In Experiment 2, analyses of the listed thoughts revealed that counterargumentation decreased, then increased, whereas topic-irrelevant thinking increased as exposure frequency increased; as expected, only topic-relevant thoughts were related to agreement. These results are interpreted in terms of an attitude-modification model in which repetition and content of a persuasive advocacy affect the type and number of thoughts generated; these thoughts, in turn, affect the attitudinal reaction to the advocacy.

In this article, we will consider the attitudinal effects of repeated exposure to persuasive communications, an area that has generated surprisingly little research by social psychologists despite its frequent occurrence in and importance to everyday life. This area is not well understood (cf. Harrison, 1977), in part because most research has focused on repetition in contexts that do not involve communication. In Zajonc's (1968) original statement on the effects of repeated exposure, evidence was provided for relationships between (a) the frequency of usage and evaluation of words, (b) the frequency of interpersonal contact and attraction, and (c) the familiarity of aesthetic stimuli (e.g., musical selections) and liking. Since then, immediate effects of mere exposure have been observed using children as well as adults (Heingartner & Hall, 1974), employing between-subjects (Moreland & Zajonc, 1976) as well as within-subjects (Crandall, 1972) designs, in field (Zajonc & Rajecki, 1969) as well as laboratory (Matlin, 1970) settings, employing pictorial magazine advertisements (McCullough & Ostrom, 1974) as well as nonsense syllables (Harrison & Hines, 1970) as stimuli, and using stimuli evaluated initially either positively or negatively (Hamm, Baum, & Nikels, 1975; Zajonc, Markus, & Wilson, 1974).

However, conditions in which the exposure–liking relationship breaks down have also been identified. When the stimulus is simple, repetition leads to either a decrease in liking (Skaife, cited in Berlyne, 1971, pp. 191–194) or an initial increase, then decrease in liking (Saegert & Jellison, 1970; Smith & Dorfman, 1975). The homogeneity of the stimulus sequence presented seems also to be an important factor. A stimulus that is presented

repeatedly within a homogeneous sequence of stimuli results typically in first increasing, then decreasing liking of the stimulus (Harrison & Crandall, 1972). Moreover, when subjects are able to expose themselves to stimuli, they first display exploratory behavior and then expose themselves repeatedly to a self-selected subset of best-liked stimuli (Brickman & D'Amato, 1975). And finally, when measurement is administered immediately after the presentations of a stimulus, exposure effects may be attenuated or obliterated (Johnson & Watkins, 1971; Stang, 1974; Stang & O'Connell, 1974).

Models of Exposure Frequency and Affect

Several theoretical accounts have been offered for these results, including (a) response competition, (b) arousal theories, (c) classical conditioning, (d) intuition as artifact, (e) expectancy arousal, (f) satiation/generation, and (g) two-factor theories (see Harrison, 1977, and Stang, 1973, for reviews). Of these interpretations, the two-factor theories provide the most flexible explanation because they "can account for any pattern of results (by drawing differentially on each factor)" (Harrison, 1977, p. 74). However, two-factor theories are not cogent unless the contribution of each factor can be described a priori.

Berlyne (1970) proposed an inverted-U relationship between familiarity and liking. The notions are that (a) two separate and opposing psychological processes, positive habituation (that is, a reduction in uncertainty or conflict) and tedium, operate simultaneously; (b) the relative strengths of each vary as a function of exposure to the stimulus; and (c) initially, the process of habituation has greater impact on liking than does tedium. Thus, repeated exposure leads initially to liking, but ultimately leads to disliking. Accordingly, stimulus complexity and sequence heterogeneity slow the positive habituation process and extend the inflection point of the inverted-U curve to higher levels of exposure.

Stang (1973, 1975) proposed an extension of Berlyne's (1970) two-factor account: Repeated exposure provides more opportunity to learn about the stimulus; this learning is presumably rewarding and leads to increased liking for the stimulus. With continued repetition of the stimulus, however, boredom or satiation develops; hence, repeated exposure leads ultimately to negative affect toward the stimulus.

Stang (1975) presented three experimental demonstrations that affect toward and learning of Turkish words and trigrams were affected similarly by exposure frequency. Although these results may indicate that learning mediated liking, there are three other possibilities. First, liking may have mediated learning rather than vice versa. Second, both learning and affect may have been mediated by a third variable. For instance, the cognitive elaboration of stimuli results in both enhanced recall (Craik & Lockhart, 1972; Craik & Tulving, 1975; Rogers, Kuiper, & Kirker, 1977; Cacioppo & Petty, Note 1) and polarized affect (Petty & Cacioppo, 1977; Petty, Wells, & Brock, 1976; Tesser & Conlee, 1975; Tesser & Leone, 1977). Stimulus learning, however, has not been related consistently to affective reactions (cf. Greenwald, 1968; Petty, 1977). Nevertheless, repeated exposure does provide the opportunity for more elaborate processing of the stimuli (Wyer, 1974, pp. 15–16). Thus, there is the distinct possibility that cognitive elaboration (or extent of semantic processing) mediates both learning and affect.

This latter interpretation may appear at odds with some of the existing research on mere exposure. Specifically, preexposure liking for the stimulus does not necessarily alter the direction or form of the exposure effect (Zajonc et al., 1974). But in the domain of persuasive communication, Petty et al. (1976) demonstrated that it is not the preexposure affect toward an advocacy but the nature of the associates (i.e., cognitive responses) elicited by the message that determines the attitudinal effect of a communication. Indeed, a slightly different form of their hypothesis has been employed in past studies of mere exposure as well (Brickman, Redfield, Harrison, & Crandall, 1972; Mitchell & Olson, 1977; Pearlman & Oskamp, 1971). For example, repeated presentations of words that elicited

either positive or negative associations resulted in a polarization of affect toward the stimuli (Grush, 1976). Finally, the third possibility is that although learning and affect show similar patterns, they are mediated *independently*.

Cognitive and Attitudinal Effects of Message Repetition: Two Studies

The current experiments focus on the relationships among attitudinal, associative, and learning effects of message repetition. These experiments differ in several important respects from previous research on message repetition and attitudes. McCullough and Ostrom (1974) found an exposure effect when they presented messages repeatedly in a magazine advertisment format to subjects. However, each presentation differed in the phrasing and ordering of the message arguments, and a different photograph and headline accompanied each presentation. Weiss (1971) presented the same argument repeatedly and found that exposure led to quicker ratings of agreement with the argument. However, to the extent that practiced responses are also quicker, Weiss's results may be irrelevant to the study of message repetition and attitudes. Finally, Wilson and Miller (1968) and Johnson and Watkins (1971) found an attitudinal effect for message repetition only on a delayed posttest. The absence of the immediate attitudinal effect is due presumably to satiation (cf. Harrison, 1977; Sawyer, in press; Stang, 1974). Thus, if a wider variety of levels of message repetition, more complex stimuli, or a more heterogeneous stimulus sequence had been studied, immediate attitudinal effects might have been observed. In the present studies, Experiment 1 was primarily methodological and exploratory in nature, serving as a test of the experimental materials and of the effects of the repetition of persuasive communications on liking and learning. Experiment 2 was designed to assess the viability of the various possible processes mediating the liking and learning effects in repetition experiments using such stimuli.

To explore more fully the predictive value of two-factor theories, experimental conditions were designed to elicit first increasing, then decreasing favorability toward the advocacy. Mere exposure research indicates that the inflection of the inverted-U function between exposure and affect occurs more quickly when stimuli are homogeneous (Harrison & Crandall, 1972) and simple (e.g., Smith & Dorfman, 1975) and ratings are made immediately after their presentation (Stang, 1974). In the present experiments, one of two persuasive communications was presented either one, three, or five times in succession, and the dependent measures were administered immediately afterwards. We expected to find that agreement with the advocacy would increase, then decrease as exposure frequency increased.

Experiment 1

Method

Subjects and procedure. One hundred thirty-three introductory psychology students participated in an experiment employing a 2 × 4 factorial design in which the position advocated (proattitudinal versus counterattitudinal) and the number of presentations (0, 1, 3, or 5) served as between-subjects factors. Subjects were tested in groups of 12 to 29 in language-laboratory cubicles constructed so that no subject could have visual or verbal contact with any other subject. During any one session, in which one level of repetition was presented, half of the subjects heard the proattitudinal message over the headphones, while half of the subjects heard the counterattitudinal message over the headphones. Following a procedure employed previously by Petty and Brock (1976), the same highly persuasive arguments, which were equally applicable to each advocacy, were used in each communication. Thus, the affective qualities of the elicited associates (Grush, 1976) or cognitive responses (Greenwald, 1968; Petty & Cacioppo, 1977) were presumably equated for the two communications.

Two groups (the zero-exposure pro- and counterattitudinal conditions) rated their agreement with a recommendation that university expenditures be increased. One group was told that the expenditures were to be financed by instituting a 25% service tax on visitor luxuries (proattitudinal position), and one group was told that a $70-per-quarter increase in student tuition would be instituted to finance the expenditures (counterattitudinal position). Ratings were made on a 15-point Likert-type scale where 15 indicated "agree completely" and 1 indicated "disagree completely."

Subjects in each of the remaining cells heard a taped message through headphones either one, three, or five consecutive times. The message contained a

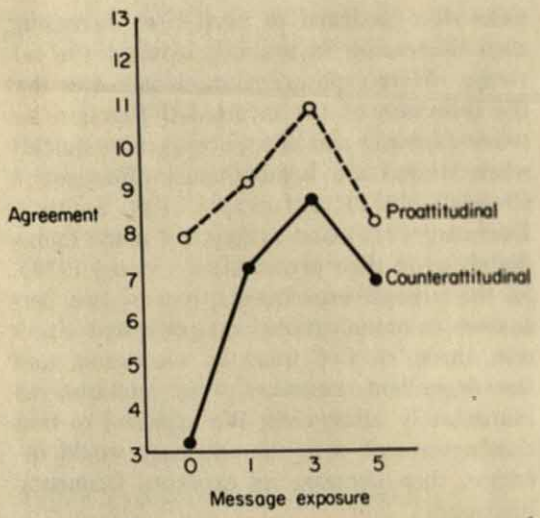

Figure 1. The effects of preexposure position and message repetition on agreement: Experiment 1.

statement that the university currently provided a substandard level of education to the undergraduates and that this problem could be remedied by increasing university expenditures. Half the subjects heard a message that contained a paragraph about instituting a 25% service tax on visitor luxuries to finance the expenditures, and half heard a message that contained a paragraph about instituting a student tuition increase of $70 per quarter to finance the expenditures. All subjects then heard the following eight arguments in favor of increasing expenditures: (a) Teaching and educational materials for students would be improved; (b) classroom sizes would be reduced; (c) handouts containing the important points in lectures could be provided; (d–f) the library facilities, job placement, and placement in graduate and professional schools could be improved; (g) better teachers could be hired; and (h) improved counseling to students, on both academic and personal matters, could be provided.

A postexperimental questionnaire containing 15-point Likert-type scales was used to assess the effects of the advocated position and message repetition on agreement with increasing university expenditures and to assess the perceived amount of distraction, effort, and involvement in the task. A recall measure was obtained after completion of the questionnaire by asking subjects to list on the last page of their booklets all of the message arguments that were presented in the communication. A judge, blind to the experimental conditions, counted an item as recalled if it correctly summarized one of the eight message arguments listed above. After completing the dependent-variable booklets, subjects were debriefed, thanked, and dismissed.

Results and Discussion

Attitude measure. The means for each cell on the attitude measure are displayed in Figure 1. It was expected that (a) subjects would agree more with the pro- than with the counterattitudinal advocacy, and (b) repetition would lead to increasing, then decreasing agreement with the advocacy. The analyses supported both hypotheses: Subjects agreed more with the pro- ($M = 9.05$) than the counterattitudinal message ($M = 6.62$), $F(1, 125) = 14.87$, $p < .001$; the number of presentations of the message affected agreement ($M_0 = 5.58$, $M_1 = 8.23$, $M_3 = 9.83$, $M_5 = 7.70$), $F(3, 125) = 7.74$, $p < .001$; and the interaction between position advocated and number of presentations did not approach significance ($p > .25$). Because the lack of an interaction indicated that the position of the advocacy (pro or counter) did not alter the effect of message repetition on agreement, trend tests were conducted on the data collapsed across position. The trend analyses were conducted according to Gaito's (1965) procedure for determining trend coefficients for unequal spacing and unequal n. A significant quadratic trend on the agreement measure, $F(1, 125) = 25.45$, $p < .001$, provided evidence of a curvilinear effect of message repetition on agreement (see Figure 1). Pairwise comparisons using the Newman-Keuls procedure for unequal n (Winer, 1971, pp. 215–218) revealed that presentations of the same persuasive message one, three, or five times led to increasing, then decreasing agreement ($ps < .05$).

Recall and ancillary measures. An analysis of the number of message arguments recalled revealed that message repetition, $F(2, 79) = 12.04$, $p < .001$, and message position, $F(1, 79) = 14.27$, $p < .001$, altered the incidental learning of the message arguments. The first main effect indicated that learning increased with repetition. The mean number of arguments recalled at one, three, and five repetitions, respectively, was 4.08, 4.67, and 6.00. The second main effect indicated that subjects recalled more message arguments when the position advocated was counterattitudinal ($M = 5.54$) than when the position advocated was proattitudinal ($M = 4.29$). Compared to previous research on selective learning (cf. Greenwald & Sakumara, 1967), Experiment 1 had the following methodological advantages:

(a) Subjects with initially similar attitudes were assigned randomly to pro- and counterattitudinal conditions rather than selecting subjects for participation on the basis of their initially different attitudes; (b) the message arguments to be learned by the different groups of subjects were identical, though they were used to support either a pro- or a counterattitudinal advocacy. Thus, the differential learning could not be attributed to the ease with which the arguments could be learned.

In addition, a Message Position × Message Repetition interaction was found, $F(2, 79) = 5.10$, $p < .01$. Specifically, the increase in recall was greatest between three and five repetitions of the proattitudinal advocacy ($p < .05$) and between one and three repetitions of the counterattitudinal advocacy (*ns*—all comparisons made using the Newman-Keuls procedure for unequal *n*).

The first experiment provided strong support for the notion that a persuasive appeal presented repeatedly in close temporal proximity leads to increasing, then decreasing acceptance of the advocacy. However, the finding that more message arguments were recalled when the advocacy was disliked initially (i.e., counterattitudinal) than when it was liked initially (i.e., proattitudinal) suggests that liking does not necessarily result in greater learning. The results of Experiment 1 are also at odds with the learning-leads-to-liking hypothesis. This is especially dramatic for the proattitudinal advocacy: The greatest increase in affect (between one and three repetitions) was associated with no change in learning, whereas the greatest learning (between three and five repetitions) was associated with a decrease in affect. A within-cell correlation (Insko, Lind, & La Tour, 1976, p. 69) between agreement and recall indicated that these variables were not related significantly ($r = -.02$).

Analyses of the ancillary measures (effort, involvement, and distraction) revealed that they were not affected by any of the manipulations.

Experiment 2

A second experiment was conducted to investigate other possible mediators of the exposure effect observed in the preceding experiment. Of particular interest in Experiment 2 was the possibility that a recipient's cognitive responses would be influenced by message repetition and would predict more accurately the subsequent attitudinal reactions than would learning. Indeed, evidence already exists for just such a hypothesis. Grush (1976) investigated the effects of repeatedly presenting infrequently used words that elicited either positive or negative associations. He found that words that elicited positive associations were evaluated more positively after repeated exposures, but that the opposite effect occurred for words that elicited negative associations. Grush proposed an attitude-formation explanation of his results. The notion is that a stimulus initially elicits only a few cognitive responses (associations). With repeated exposure, subjects generate increased (or increasingly consistent) cognitive responses to the stimulus (thus, it is similar in some respects to the response competition interpretation). The final evaluation of an exposed stimulus is assumed to be a function of the summed evaluations of the cognitive responses it elicits. If the responses are generally favorable, increased exposure should lead to a more positive evaluation of the stimulus, but if the responses are generally negative, increased exposure should lead to a less favorable evaluation of the stimulus.

Miller (1976) investigated the effects of mere exposure using communicative stimuli (posters containing a political message) and found that moderate but not high levels of exposure led to attitude change (increased agreement). Miller argued that the high exposure loads caused individuals to feel that their personal freedom was being restricted, and reactance (Brehm, 1966) led to resistance to persuasion. It is equally possible, on the other hand, that an unpleasant state of satiation (e.g., boredom) developed at the high exposure levels. These models suggest that the cognitive responses (i.e., counterarguments, favorable thoughts, neutral/irrelevant thoughts) elicited in a repetition experiment may mediate the affective reactions to the stimulus. However, no study to date that has employed repetitions of the same persuasive

communications has investigated the nature or the temporal sequence of the cognitive responses elicited. Thus, in Experiment 2 subjects heard the previously tested pro- or counterattitudinal advocacy either one, three, or five times in succession. Afterwards, subjects (a) were instructed to list everything about which they had thought during the preceding minutes, (b) rated their attitude toward the advocacy and completed ancillary measures, and (c) responded to a measure of the incidental learning of message arguments.

Method

One hundred ninety-three introductory psychology students participated in an experiment employing a 2 × 3 factorial design in which the position advocated (pro- versus counterattitudinal) and the number of presentations (1, 3, or 5) served as between-subjects factors.[1] As in Experiment 1, subjects were tested in groups of 12 to 29 in cubicles in a language laboratory. During any one session, in which one level of repetition was presented, half the subjects heard the proattitudinal and half the subjects heard the counterattitudinal message through headphones. Subjects rated their agreement with increasing university expenditures on a 15-point Likert-type scale and completed the postexperimental questionnaire. In a procedure adapted from Brock (1967) and Greenwald (1968) and employed previously by Petty and Cacioppo (1977), subjects were given 3 minutes to list the actual thoughts that occurred to them during the presentations of the communication they had heard. Subjects were then asked to go back through the thoughts they had listed and to place a plus (+) next to each thought that supported the advocacy, a minus (−) next to each thought that attacked the advocacy, and a zero (0) next to each thought that was neutral or irrelevant to the advocacy. Subjects were then asked to list all of the message arguments they could recall. (Recall was scored in the same manner as in Experiment 1.)

Two judges who were blind to the experimental conditions rated the cognitive responses. Counted as unfavorable thoughts (i.e., counterarguments) were statements directed against the advocated position that mentioned specific unfavorable consequences, statements of alternative methods of raising money, challenges to the validity of arguments in the message, and statements of affect opposing the advocated position. Counted as favorable thoughts were statements in favor of the advocated position that mentioned specific favorable consequences, statements ruling out alternatives, statements that supported the validity of the message arguments, and statements of affect supporting the advocated position. All other listed items were rated as neutral/irrelevant thoughts. Similar items were counted as one thought. Judges agreed on over 95% of the ratings; disagreements were resolved through discussion.

Results

Attitude measure. The mean for each cell on the attitude measure is graphed in Figure 2. As in Experiment 1, subjects agreed more with the pro- ($M = 9.61$) than the counterattitudinal advocacy ($M = 8.19$), $F(1, 187) = 6.48$, $p < .02$, and subjects agreed differentially as a function of the number of message repetitions ($M_1 = 8.09$, $M_3 = 9.77$, $M_5 = 8.86$), $F(2, 187) = 3.04$, $p < .05$. The interaction again did not approach significance ($p > .20$). Trend tests were conducted using Gaito's (1965) procedure for unequal n and revealed that message repetition resulted in a significant quadratic effect, $F(1, 187) = 9.86$, $p < .001$. Pairwise comparisons of cell means using Newman-Keul's procedure for unequal n provided evidence that agreement with the advocacy increased ($p < .05$), then decreased only marginally ($p < .10$) as exposure frequency increased.

Cognitive-response measures. The means for each cell on the cognitive-response measures are graphed in Figure 2. Overall analyses of variance revealed that subjects generated more counterarguments, $F(1, 187) = 10.71$, $p < .001$, and fewer neutral/irrelevant thoughts, $F(1, 187) = 4.35$, $p < .05$, in response to the counterattitudinal than in response to the proattitudinal advocacy. The number of message repetitions marginally affected the production of favorable, $F(2, 187) = 2.36$, $p < .10$, and neutral/irrelevant, $F(2, 187) = 2.61$, $p < .08$, thoughts. There were

[1] An additional factor included in the design was whether subjects were informed as to how many times they would hear the message prior to exposure. That is, half of the subjects were told that they were to hear a taped message one, three, or five times (the number being determined by the number of times they actually heard the message) so that they might have time to consider completely the taped communication. The other half of the subjects were told nothing about the number of times the communication would be presented. Analyses revealed that this factor made no difference on any of the measures obtained, and it will not be discussed further.

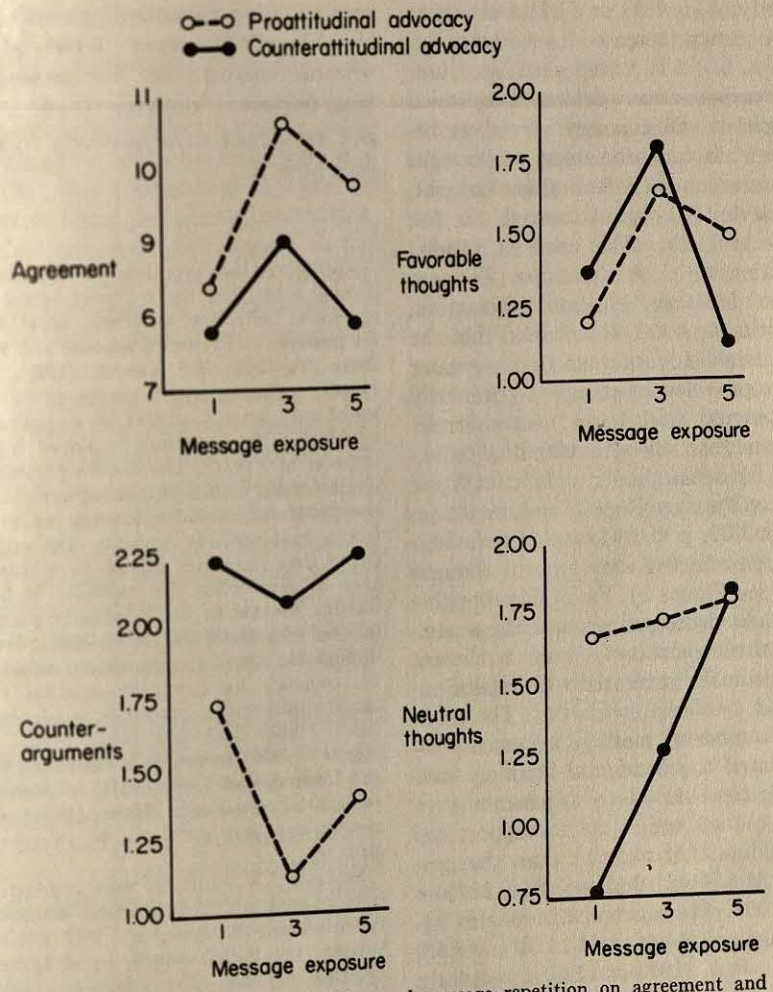

Figure 2. The effects of preexposure position and message repetition on agreement and cognitive response: Experiment 2.

no significant interactions; thus, trend contrasts were computed on the data collapsed across message position. The results of trend contrasts on each cognitive-response measure (employing Gaito's procedure for unequal n) indicated that counterargumentation was affected quadratically, $F(1, 187) = 15.37$, $p < .001$, and neutral/irrelevant thinking was af-

Table 1
Within-Cell Correlations: Experiment 2

Variable	Agreement	Counter-arguments	Favorable thoughts	Neutral thoughts
Counterarguments	−.56			
Favorable thoughts	.45	−.45		
Neutral thoughts	.03	−.28	−.16	
Recall	−.01	.17	−.07	.02

fected linearly, $F(1, 187) = 5.87$, $p < .02$, as exposure frequency increased (see Figure 2).

Finally, a $2 \times 3 \times 3$ repeated measures analysis of variance was performed in which message position and exposure served as between-subjects factors and type of thought (i.e., counterargument, favorable thought, neutral/irrelevant thought) served as the within-subjects factor. The analysis yielded two interactions: (a) A significant Type of Thought $\times$ Message Position interaction, $F(2, 370) = 6.14$, $p < .003$, revealed that the counterattitudinal advocacy elicited a greater number of topic-relevant thoughts (primarily counterarguments) and fewer neutral/irrelevant thoughts than the proattitudinal advocacy; and (b) a marginally significant Type of Thought $\times$ Message Repetition interaction, $F(4, 370) = 2.02$, $p < .09$, showed that message repetition affected each type of thought differently (see Figure 2). Favorable thoughts increased, then decreased; counterarguments decreased, then increased; and irrelevant thoughts continually increased with repetition.

Recall and ancillary measures. The analysis of the number of message arguments recalled replicated the incidental learning finding in Experiment 1: More arguments were recalled when they were used to support the counterattitudinal ($M = 5.51$) than the proattitudinal ($M = 4.48$) position, $F(1, 187) = 14.63$, $p < .001$. Message repetition also affected message recall ($M_1 = 4.14$, $M_3 = 5.50$, $M_5 = 5.36$), $F(2, 187) = 11.49$, $p < .001$; the interaction, however, was not significant this time. Trend analyses (collapsed across message position) yielded significant Fs for both the linear, $F(1, 187) = 14.14$, $p < .001$, and quadratic, $F(1, 187) = 15.01$, $p < .001$, trends.

The analyses of the ancillary measures revealed again that neither the position advocated nor the number of presentations affected any of these ratings.

Within-cell correlations. A within-cell correlation between each pair of dependent measures was calculated to provide measures of association between the variables with the effects of the treatments held constant. The results of these analyses are presented in Table 1. Note that agreement and topic-relevant thinking (counterarguments and favorable thoughts) were interrelated highly, whereas learning of the message (recall), topic-irrelevant thinking (neutral thoughts), and agreement were relatively independent of each other.[2]

---

[2] Although the hypothesized attitude-modification process holds that the cognitive responses mediated agreement with the advocacy, other causal chains are possible. Following Osterhouse and Brock (1970), Insko, Turnbull, and Yandell (1974), Petty et al. (1976), and Petty and Cacioppo (1977), four analyses of covariance (ANCOVA) were conducted. The rationale for the procedure employed is discussed by Insko et al. (1974). The ANCOVA procedure compares specific causal models by holding constant statistically the postulated mediator between an initial variable and a final criterion variable. The relationship between these measures should be within error variance of zero when the mediator is held constant through the use of the covariance procedure; a reduction of a significant F for the criterion measure through the use of this procedure would suggest that the covariate mediated the criterion variable. The causal-model-testing procedure is adapted from Blalock's (1964) technique using partial correlations, Scheffé's (1959) technique of examining partial slopes, and Cochran and Cox's (1957) technique employing analysis of covariance. Heise (1969) discusses the assumptions and problems of causal-model-testing analyses.

Separate 2×3 ANCOVAs were conducted using (a) counterarguments, (b) favorable thoughts, (c) neutral/irrelevant thoughts, and (d) recall as the covariate (i.e., initial variable) and agreement as the criterion variable. The originally significant F of 3.02 for the repetition main effect on agreement was reduced to Fs < 1 when counterarguments and favorable thoughts served as the covariate. When neutral/irrelevant thoughts served as the covariate, the F of 3.02 was reduced to a marginally significant F of 2.41; when recall served as the covariate, the F for agreement remained significant at 11.24. When these analyses were repeated with agreement serving as the covariate, the marginally significant F of 2.36 for the repetition main effect on favorable thoughts was reduced slightly to 1.78; the marginally significant F of 2.61 on neutral/irrelevant thoughts became a significant F of 6.04; the nonsignificant F of 1.57 on counterarguments remained a nonsignificant F of .68; and the highly significant F of 11.49 on recall remained a significant F of 5.80. Interpretation of these analyses should be cautious, since the reliabilities of the measures are unknown. Nevertheless, the results are consistent with the notion that topic-relevant thinking mediates the effect of repetition on attitude, and they are inconsistent with the learning-leads-to-liking hypothesis.

Discussion

Although various research, including Experiment 2, has demonstrated that repetition influences learning and affect similarly, additional evidence provided in Experiments 1 and 2 suggests that this relationship in mere exposure research using persuasive communications is neither the result of learning leading to liking nor of liking leading to learning. Specifically, the within-cell correlations between learning and agreement in the experiments were near zero and nonsignificant. Additionally, the analyses of covariance (Footnote 2) suggested that although learning did not mediate agreement, the cognitive responses elicited by the communications did. Of course, it is possible that the learning-leads-to-liking hypothesis in mere exposure research applies only to stimuli that possess few cognitive associations (e.g., nonsense stimuli). The present experiments provide no evidence from which to evaluate this hypothesis.

The present experimental results indicated that regardless of the position advocated, message repetition led to (a) increasing, then decreasing agreement with the advocacy; (b) decreasing, then increasing counterargumentation; and (c) increasing topic-irrelevant thinking. Of importance is that the analyses of variance revealed that the sequence of the topic-relevant thoughts generated in response to the repeated messages paralleled the observed attitude change. It was hypothesized that the effects of message repetition on agreement were mediated by a two-stage attitude-modification process in which the repetition of the message arguments provided more opportunities to elaborate cognitively upon them and to realize their cogency and favorable implications. Hence, counterargumentation declined at the moderate exposure frequency. At high exposure levels, however, tedium and/or reactance may have motivated the individual to again attack the now offensive communication. Thus, counterargumentation was renewed, and agreement decreased at high exposure levels.

Validity of thought listings. It might be argued that the thought listings do not provide evidence about the nature of the subjects' thoughts, but instead reflect what subjects thought the experimenter wanted them to list (Orne, 1962). This interpretation is considered unlikely in the present case because (a) the experimenter clearly *requested* a list of everything about which subjects had been thinking during the message; (b) although a complex pattern of counterargumentation was produced (first decreasing, then increasing), reports of topic-irrelevant thinking increased as exposure frequency increased; and (c) a between-subjects design was employed, making unlikely the successful intuiting of the experimenter's hypotheses. Furthermore, the position of the advocacies did not alter the exposure effects on the listed thoughts and attitude; although this result replicates previous research on mere exposure (Zajonc et al., 1974), it is unlikely that such an effect is common knowledge to naive subjects.

It might also be argued that subjects are unable to provide veridical information about the nature of their thoughts. Cacioppo, Harkins, and Petty (in press) and Cacioppo and Petty (Note 2) have argued that subjects are able to report accurately their recent and current thoughts and ideas and that the fact that subjects may be unaware of the *reasons for*, or *consequences of*, their thoughts (cf. Nisbett & Bellows, 1977; Nisbett & Wilson, 1977) does not invalidate the use of their responses in a content analysis. A thought-listing analysis assumes only that the thoughts and ideas of subjects are as accessible as are attitudes, judgments, facts, and so on (cf. Wyer, 1974). The burden then lies with researchers to determine whether a subject's cognitive responses are predictive of, or influential in, affect and behavior. It should be noted that although the present results are consistent with the hypothesized attitude-modification process and inconsistent with the learning-affect model, no definitive evidence concerning the causal role of cognitive responses is provided. Future research might fruitfully employ distraction to attenuate the dominant type of thought generated and/or vary message-argument quality to differentiate the nature of the dominant thought elicited.

Cognitive dynamics of message repetition. We have proposed that message repetition guides a sequence of cognitive reactions to a persuasive communication. But are the repeated presentations of the stimulus per se responsible for this sequence? We think not. It should be apparent that in the present experiments, the number of repetitions of a message was confounded with the available time to think about the message arguments, generate new topic-relevant thoughts, and so forth. This (additional) time to think has been shown to be necessary for individuals to process more deeply and elaborate more fully the content of an impending communication (Petty & Cacioppo, 1977), the persuasive arguments for a group decision (Burnstein & Vinokur, 1975, 1977), and the qualities of a stimulus (Tesser & Leone, 1977). For example, Tesser and his colleagues (e.g., Sadler & Tesser, 1973; Tesser & Conlee, 1975) have demonstrated that if persons are asked to think about some object or issue, the amount of time spent thinking is related to the amount of attitude polarization that results. Thus, objects that are liked initially are evaluated more favorably with increased thought, and initially disliked objects are evaluated more negatively. If we had simply presented subjects with the topics of the pro-attitudinal (increasing expenditures by instituting a visitor's tax) and counterattitudinal (increasing expenditures by increasing tuition) advocacies, *without the accompanying persuasive arguments,* we expect that we would have replicated the attitude polarization effect: More time to think would have produced increased agreement with the pro-attitudinal and decreased agreement with the counterattitudinal advocacy. However, we found that moderate repetitions of (and time to think about) the persuasive message arguments led to increased agreement with both the pro- and counterattitudinal advocacies. This finding supports the notion that the first stage of the attitude-modification process of message repetition involves enhanced opportunities to process the *content* of the message (which was the same for both pro- and counterattitudinal groups). Moreover, we found that high exposure frequencies of (and lengthier time to think about) the message arguments resulted in decreased agreement with the advocacy. This result is consistent with the notion that the second stage of the attitude-modification process involves the development of tedium and/or reactance, which modifies the subsequent information-processing activity.

We assumed that individuals would be motivated to process personally involving stimuli (cf. Cialdini, Levy, Herman, Kozlowski, & Petty, 1976); thus, we employed communicative stimuli that were personally relevant to the individuals in the experiment. We also assumed that these individuals, if able, would be motivated to elaborate more fully the arguments contained in each advocacy. Thus, the provision of additional opportunities via message repetition to process the persuasive arguments contained in the advocacies would result in greater realizations of their validity, and not until the repetitions became excessive would this process yield to one motivated by reactance or tedium.

However, there are at least two other ways to account for the observed sequence of cognitive responses. First, since each of the arguments contained in the advocacies was in favor of an increase in spending, this general orientation may have served as a retrieval cue for initially accessing and generating topic-relevant cognitions that further supported an increase in spending. As the memorial pool of favorable thoughts was depleted, however, counterarguments would become increasingly accessible. Hence, according to this account, the *direction* of the message arguments is important rather than their cogency or persuasiveness.

A second plausible mechanism has been discussed by Burnstein and Vinokur (1975, 1977). The simple statement that others are advocating a position discrepant from one's own "may induce a person to reconstruct a line of reasoning which he thinks could have produced such (an advocacy)" (Burnstein, Vinokur, & Trope, 1973, p. 244). This model differs from Tesser's in that in this instance, the individual is motivated to consider, at least initially, all possible arguments that support the advocacy, since it has been made

salient to the individual that others endorse this view. Again, as the proargument pool in memory is exhausted, counterarguments become increasingly accessible. While this position is similar in many respects to our own, we place a greater emphasis on the cognitive responses elicited by the content and context of message repetition.

Cognitive dynamics and incidental recall. Finally, a word might be said about the incidental recall findings of Experiments 1 and 2. In each experiment, it was found that persons recalled more message arguments used to support a counterattitudinal than a proattitudinal position. Neither familiarity nor novelty can account for this effect, because the *same* message arguments were used to support each position. Nor can a consistency explanation account for this effect, because best remembered were the arguments used to support a position *inconsistent* with the beliefs of the subjects.

Perhaps a more cogent account of the incidental recall findings can be provided by an analysis of the extent of processing of the pro- and counterattitudinal advocacies. Accumulated research has supported Craik and Lockhart's (1972) proposal that the depth or extent of processing influences the recall of a stimulus (e.g., Craik & Tulving, 1975; Rogers et al., 1977; Cacioppo & Petty, Note 1). It is interesting to note in light of this evidence that as discovered in Experiment 2, the counterattitudinal advocacies elicited a greater number of *topic-relevant thoughts* than did the proattitudinal advocacies. This effect was obtained even though the message arguments comprising each advocacy were identical. If one assumes that the number of listed topic-relevant thoughts indicates the extent to which the individuals elaborated cognitively upon the message arguments, then superior recall of the message arguments supporting the counterattitudinal rather than the proattitudinal advocacy would be expected. The results are in accord with this analysis.

Effects of Controllable Versus Uncontrollable Factors on Responsibility Attributions: A Single-Subject Approach

Daniel Arkkelin, Thomas Oakley, and Clifford Mynatt
Bowling Green State University

A "lens-model" methodology was used to assess the influence of different informational "cues" on responsibility attributions for an automobile accident. Multiple regression analyses indicated that although there were large individual differences, in Experiments 1 and 2 the major determinants of responsibility judgments were car speed and the condition of the car's brakes. In Experiment 3, speeding and brakes information was deleted. The major determinant of attributions was the driver's past record, although the importance of severity of consequences was somewhat greater than in the first two experiments. In Experiment 4, driving record was deleted. The majority of subjects indicated that not enough information was available. Overall, severity was a relatively unimportant cue. Observers tended, instead, to rely on factors over which the driver had control. The lens-model approach seems quite suitable for studying attributional judgments, particularly since it provides a detailed description of individual judgment strategies.

Attribution research has typically utilized experimental designs in which only a limited number of attributional determinants are manipulated. Additionally, between-subjects statistical analyses are used in which individual differences are treated as "error variance." The present studies were conducted to explore an alternative approach that permits the assessment of the effects of several independent variables and the determination of the relative importance of each variable for individual subjects.

Fischhoff (1976) has pointed out that attribution theory is not the only area of psychological research concerned with inferential behavior. An attribution can be conceptualized as a special case of a general judgment process wherein individuals integrate information to arrive at judgments.

The authors would like to express their appreciation to Michael Doherty for his assistance throughout the project and for his comments on an early draft of the manuscript.

Requests for reprints should be sent to Daniel Arkkelin, who is now at the Department of Psychology, Wartburg College, Waverly, Iowa 50677.

Investigators of human judgment have used multiple regression analysis extensively to quantitatively describe the manner in which informational cues are weighted and combined by a judge to make a decision (Slovic & Lichenstein, 1971). Brunswik's (1952) lens model has served as the framework for many of these investigations (see Dudycha & Naylor, 1966; Hammond, Stewart, Brehmer, & Steinmann, 1975). Keeley and Doherty (1971) describe the typical paradigm in which a set of cues, X_i, are presented to a decision maker, whose response, Y_s, varies as a function of the cue values. The individual makes a large number of judgments in response to various combinations of the cue values. Multiple regression analysis is then applied to "capture the policy" of the judge, resulting in a regression equation that is a model of the judge's integrating and weighting strategy, or policy. Specifically, the regression weights are indexes of the extent to which the judge employs each cue.

Since the relative size of the regression weights is partially determined by their ordi-

Copyright 1979 by the American Psychological Association, Inc. 0022-3514/79/3701-0110$00.75

nal position in the regression equation when cues are intercorrelated, Darlington's (1968) "usefulness index" is commonly used to assess the relative importance of each cue. This index is the amount R^2 decreases if a given cue is deleted and the regression equation recalculated. The usefulness indexes can then be tested for statistical significance.

While this methodology can be applied to any area of attribution research, attribution of responsibility for an accident was chosen for the present investigations, since there are several unresolved questions concerning this topic. Several investigators have reported that observers tend to assign increasing responsibility to a target person as the severity of an accident increases (e.g., Chaiken & Darley, 1973; McKillip & Posavac, 1975; Shaver, 1970; Walster, 1966). Other studies have not replicated this effect (e.g., Shaver, 1970; Walster, 1967). Additionally, researchers have not reported the *magnitude* of the severity effect when it has occurred or its *relative* magnitude in comparison to other potential attributional determinants. The following experiments used the lens-model methodology to assess the relative influence of seven cues on individual observers' responsibility attributions.

Experiment 1

Method

Subjects. Ten students recruited from introductory psychology classes served as subjects.

Materials. Pilot subjects were asked to list what information they would need to determine a driver's responsibility for an automobile accident. The most frequently requested items were road conditions, traffic conditions, the driver's past record of accidents, car speed, and the condition of the brakes of the driver's car. In addition to these "cues," two others, severity of consequences to victims and severity of consequences to the driver, were included in the cue set.

Statements describing two levels of each cue were constructed (e.g., high or low severity of consequences, light or heavy traffic, etc.) resulting in 128 combinations of the cues. An example of one particular combination follows:

> While driving to work last week, Elaine W. was involved in an automobile accident. Elaine was unharmed, but the people in the other car were critically injured. The stretch of road on which the accident occurred was full of potholes, and there was very little traffic at the time of the accident. Elaine's record indicates that she has been in several accidents since she got her driver's license. It was determined that at the time of the accident she was not speeding and that the brakes on her car were in need of repair. On the basis of the above information, how responsible do you think Elaine should be held for the accident?

A 7-point scale was at the bottom of each profile, with the statement "not at all responsible" at the left extreme and "completely responsible" at the right extreme.

Since multiple regression analysis does not require that all possible cue combinations actually be presented to the subjects, 40 of the 128 profiles were randomly selected, and booklets containing the chosen profiles were constructed. The booklets contained the following frequencies of each level of each cue: severity-driver (high = 20, low = 20); severity-victim (high = 20, low = 20); road conditions (good = 19, poor = 21); traffic (light = 23, heavy = 17); driving record (good = 13, poor = 27); speed (excessive = 14, moderate = 26); brakes (good = 12, poor = 28).

Procedure. Each subject was given a booklet of profiles and a cover sheet indicating that each page contained a short story, with the pattern of information differing from page to page. Subjects were asked to make a judgment about the driver on the scale at the bottom of each page and instructed not to look back at their previous judgments.

Results

The numerical values (0 vs. 1) of the two levels of each cue were entered as predictor variables in a stepwise multiple regression analysis of each subject's 40 responsibility judgments. Table 1 presents the R^2 values ($M = .66$) and significant ($p < .05$) usefulness indexes (UI) for each subject.[1]

Inspection of this table reveals a marked reliance on the cues of speeding (9 of 10 subjects employed this cue to a significant extent, $M_{UI} = .31$) and brakes (9 subjects, $M_{UI} = .27$). Information regarding consequences to victims was relied upon to a significant extent by only one subject ($M_{UI} = .01$), and information about consequences to the driver was not employed by any subject.

Two conclusions are clearly warranted from Table 1: (a) Subjects' "policies" were

[1] Table 1 is included to provide an example of how data obtained with this technique are typically summarized. Tables for the remaining experiments are available from the first author upon request.

Table 1
Usefulness Indexes (UI) of Each Cue for Each Subject in Experiment 1

Subject no.	Cue							
	Severity (driver)	Severity (victim)	Road conditions	Traffic	Record	Speeding	Brakes	R^2
1				.09		.35	.44	.70
2							.23	.35
3			.06	.05		.21	.51	.66
4			.06	.08		.23	.30	.60
5						.32	.42	.75
6		.07				.46	.08	.65
7					.09	.31	.31	.84
8						.40	.09	.56
9					.08	.49		.73
10				.04		.34	.33	.75
Frequency	0	1	2	4	2	9	9	
M_{UI}	.00	.01	.01	.03	.02	.31	.27	

Note. No entry indicates that the usefulness index was not significant ($p < .05$).

similar, to the extent that 8 of 10 people utilized both speeding and brakes information to a significant degree, whereas severity of consequences to either the driver or victims was of minimal importance; and (b) there were large individual differences regarding both the magnitude of importance of particular cues and which cues were relied upon by any given subject.

Experiment 2

Method

Since speeding and brakes were last in order of appearance in each story and consequences to driver and victims occurred first and second, it seemed possible that the striking reliance on speeding and brakes may have been an artifact of serial position (i.e., a "recency effect"). Thus, Experiment 1 was replicated using the same profiles, except that consequences to the driver and victims appeared last and next to last in each story, while speeding and brakes were second and third in order of appearance. Ten introductory psychology students were presented the new booklets, following the same procedure as in Experiment 1.

Results

The R^2 values were similar to those obtained in Experiment 1 ($M = .72$). The overwhelming importance of speeding and brakes information observed in Experiment 1 was again apparent. All subjects utilized speeding information to a significant extent ($M_{UI} = .41$). Seven subjects employed information about brakes ($M_{UI} = .10$). Thus, the possibility of an artifact due to serial position does not seem likely. The frequency of usage of consequences was somewhat greater than in Experiment 1 (four subjects employed consequences to victims, $M_{UI} = .06$; two subjects employed consequences to the driver, $M_{UI} = .02$), but the importance of these cues was still much less than that of speeding and brakes.

Experiment 3

Method

Since the first two experiments indicated that speeding and brakes were the major determinants of responsibility attributions, and given the slight increase in the frequency of utilization of consequence information in Experiment 2, it was of interest to determine whether severity of consequences would become a major determinant of attributions if speeding and brakes information were not available. Hence, new profile booklets were constructed in which the speeding and brakes cues were deleted from the same 40 profiles employed in Experiment 2 (i.e., severity information still appeared last in the stories), and 10 additional subjects were asked to make responsibility judgments about these stories.

Results

The R^2 values were again similar to those of the first two experiments ($M = .60$). Examination of the significant usefulness indexes revealed that the most important de-

terminant of attributions was driving record (eight subjects employed this cue to a significant extent, $M_{UI} = .41$). Severity of consequences to the victims was the second most important cue (five subjects, $M_{UI} = .05$). Severity of consequences to the driver was used by only one subject.

Experiment 4

In order to determine how important severity of consequences would be in the absence of information regarding speeding, brakes, and driving record, 10 more subjects were presented the same 40 profiles, in which driving record was now deleted as well. Four of these subjects circled *1*s (i.e., "not at all responsible") on all profiles, and two subjects circled all *4*s (i.e., the midpoint on the scale). These subjects also indicated on an open-ended postexperimental questionnaire that there was not enough information available on which to base their judgments. Of the remaining four subjects, the R^2 for one was nonsignificant, and there was no identifiable pattern of cue utilization for the other three subjects.

General Discussion

Role of Severity in Responsibility Attribution

The results of Experiments 1 and 2 clearly indicate that the two most important determinants of attributions were the cues regarding whether the driver was speeding prior to the accident (19 of 20 subjects employed this cue to a significant degree) and whether the brakes of the car were in good or poor condition (16 of 20 subjects). The importance of these two cues was far greater than that of severity of consequences to the victims (5 subjects) or severity of consequences to the driver (2 subjects). This underscores the conclusion drawn by Shaver (Note 1) that "overall severity-dependent responsibility attribution (is) the exception rather than the rule" (p. 9).

Role of Controllable Versus Uncontrollable Factors

It is interesting that the two most frequently utilized cues (speeding and brakes) were factors directly under the driver's control. That is, an individual can be expected to take responsibility for driving at a safe speed and for maintaining the brakes of his or her car. On the other hand, factors such as road and traffic conditions or the severity of the consequences of an accident are not under a person's direct control. It is also interesting that few subjects employed more than two or three of the seven possible factors. It appears that most subjects simply chose to attend to that information which they deemed to be most relevant to the problem of assigning responsibility for the accident, while ignoring the other cues. When the two most relevant cues were eliminated, subjects relied almost unanimously on driving record (8 of 10 subjects). In accord with the hypothesis that observers rely on information regarding factors over which the driver has control, the overall importance of driving record in Experiment 3 is not surprising, since this was the only factor present over which the driver could be thought to have *any* control (in the sense of suggesting, for example, carelessness). The tendency for subects to rely on factors that are under the driver's control is consistent with Lerner's (1970) proposition that we have a need to believe that people deserve bad things that befall them, as well as with Wortman's (1976) argument that we make attributions in order to enhance our feelings of control over the environment.

Methodological Issues

In interpreting the results of the present experiments, several methodological caveats should be borne in mind. First, the relative "importance" of the various factors manipulated may be due not to the factors themselves but to the *range* of levels employed (i.e., the particular wording used to specify the different levels). Different wording might have produced a very different ordering of the variables in terms of importance (see Ebbesen & Konečni, 1975). Although the levels employed here seem representative of high and low values, it might be useful to consider several different levels in future research. Additionally, a different pattern of cue utilization may be obtained with other dependent

measures (e.g., sanction or guilt; cf. Fishbein & Ajzen, 1973; Vidmar & Crinklaw, 1974). It is also possible that judges may integrate cues in an interactive fashion. However, the R^2 values obtained here indicate that the majority of the variance in responsibility judgments was accounted for by a linear combination of the cues, and there is little evidence in the literature on human judgment and decision making of nonlinear cue utilization (Goldberg, 1968, 1970). Nevertheless, interaction terms can be included in the multiple regression equation (Kerlinger & Pedhazur, 1973).

Finally, there is some evidence in our data for a serial position effect on severity utilization. That is, consequences appeared to be somewhat more readily utilized when they came last in serial order than when they came early. Recent work dealing with children's moral judgments (Austin, Ruble, & Trabasso, 1977; Feldman, Klosson, Parsons, Rholes, & Ruble, 1976) has demonstrated a recency effect on consequence utilization due to presentation order. While this result suggests a possible resolution for the inconsistencies in past responsibility attribution research (i.e., perhaps consequences information was presented last in those experiments reporting the severity effect, whereas it may have been presented first in those studies failing to find the effect), a review of the procedures of past research indicates that this is not the case (cf. Chaiken & Darley, 1973; McKillip & Posavac, 1975; Medway & Lowe, 1975; Shaver, 1970; Stokols & Schopler, 1973; Walster, 1966). Also, no serial position effect was observed for speeding and brakes utilization, and that observed for severity was minimal. However, the small effect does suggest that perhaps future research should counterbalance the serial position of a particular cue.

Applicability of the Lens-Model Approach

More important than the specific implications of these findings for responsibility attribution are the general implications of the lens-model approach. The usefulness of this methodology seems apparent. It permits the parsimonious assessment of proportions of variance accounted for by a large number of attributional determinants for *individual subjects*, thus providing a way to systematically investigate individual differences. For example, individuals may differ in their tendency to rely on severity of consequences in assigning responsibility for an accident. In fact, our experiments suggest that this may indeed be the case. Even among subjects who relied on severity, some used this cue to a great extent, whereas others relied on it very little. Such individual differences (as well as differences with respect to how *other cues* are employed) could be subjected to experimental investigation, perhaps leading to the identification of attributional "styles" and the construction of theories regarding the characteristic manner in which people integrate information in making attributions.

Marital Roles, Sex Differences, and Interpersonal Attraction

Joseph E. Grush
Northern Illinois University

Janet G. Yehl
University of South Carolina at Spartanburg

This investigation tested the hypothesis that role and dispositional factors can alter the usual link between similarity and attraction. In two replications, females and males with traditional or nontraditional attitudes toward sex roles and marriage rated similar or dissimilar opposite-sex strangers on three attraction measures. Results showed that sex and traditionality interacted with similarity in determining ratings of the strangers' general likability and personal role attraction (e.g., desirability as a dating partner), but not their functional role attraction (e.g., desirability as a debater on sex roles). The discussion suggests that previous attempts to find interactions have often failed because of a lack of correspondence between dispositional factors and similarity manipulations. The discussion also suggests that reinforcement and informational explanations could account for the overall findings, but that communication factors of extremity and discrepancy could not.

Investigators using Byrne's (1971) attraction paradigm have generally found a strong positive relationship between attitude similarity and interpersonal attraction. This relationship has been found for different modes of stimulus presentation (Byrne & Clore, 1966), different populations (Byrne, Griffitt, Hudgins, & Reeves, 1969), and different issues of varying levels of importance (Clore & Baldridge, 1968). The generalizability of the similarity–attraction relationship has been further demonstrated by investigations that have manipulated similarity on the basis of abilities (Zander & Havelin, 1960), economic status (Byrne, Clore, & Worchel, 1966), emotional states (Zimbardo & Formica, 1963), and personality traits (Byrne, Griffitt, & Stefaniak, 1967).

According to Clore and Byrne's (1974) reinforcement–affect model, attraction toward another person is determined by the proportion of reinforcements and punishments associated with that person. Although similarity between judge and target has frequently been found to be reinforcing, the focus of the model is on interpersonal reinforcement rather than similarity per se. Thus, a recent corollary of the model postulates that role and dispositional factors can alter the usual similarity–attraction relationship by altering the reinforcement contingencies associated with another person (Clore & Byrne, 1977).

In the corollary, roles refer to societal positions in which the occupant is expected to behave in certain prescribed ways. Thus, certain roles may attenuate the reinforcing properties of similarity because the expectations for those roles do not include similarity. Dispositions refer to consistent differences among individuals in their orientation toward responding to the same stimulus. Thus, individuals with different socialization (reinforcement) histories may differ in their attraction responses to stimulus persons who are similar or dissimilar to themselves.

The present investigation was designed to test whether role and dispositional factors would moderate the impact of similarity on attraction. Female and male students, with traditional or nontraditional attitudes toward marital roles, judged opposite-sex strangers who had similar or dissimilar attitudes. Tra-

The authors would like to thank David Sujak and Linda Fort for their help in completing the preliminary study and Kathleen Keeley for her timely suggestions and competent assistance in conducting the laboratory experiment.

ditionality was determined by scores on a marital role decisions questionnaire that is described later (see Preliminary Study). Traditional respondents, for example, believe that wives should be concerned with child rearing and domestic matters, whereas husbands should focus on career and financial matters. Nontraditional respondents believe that these roles should be jointly shared by both spouses. Judgments of the opposite-sex strangers were made on measures of *personal role attraction* (e.g., desirability as a marriage partner), *functional role attraction* (e.g., desirability as a debater on marital roles), and *general attraction* (i.e., likability).

The personal and functional role attraction measures were included to assess different types of (anticipated) interactions between judge and target. Personal role items assessed attraction in role relationships in which judge and target would directly interact at a personal or intimate level. Functional role items assessed attraction in role relationships in which the judge would primarily observe and evaluate the target person's performance of certain public roles. Finally, the general attraction item was included to determine if global attraction tends to mirror personal or functional role attraction.

The major hypothesis was that sex and traditionality of the judges would interact with similarity of the target persons in determining personal and general attraction but not functional attraction. This hypothesis was made up of three distinct predictions relating to the three attraction measures.

Prediction 1 was that nontraditional females and traditional males would display a distinct preference for similar partners on personal role attraction, whereas traditional females and nontraditional males would not. This prediction was based on the assumption that nontraditional women and traditional men have irreconcilable differences that would lead to constant conflicts and make personal relationships between the two quite punishing. Prediction 1 also assumed that traditional women and nontraditional men could find similar or dissimilar partners equally reinforcing in personal roles but for different reasons. With similar partners, reinforcement would come from the mutuality of shared beliefs. With dissimilar partners, traditional women would find it reinforcing to know, for example, that they could pursue careers and receive help at home if they so desired. Nontraditional men would find it reinforcing to know, for example, that they could fully pursue their own careers and avoid the drudgery of household chores if they chose to do so.

Prediction 2 was that general attraction would parallel personal role attraction. This prediction was based on research that shows that general likability tends to mirror role attraction when the latter involves direct interactions between judge and target (Grush, Clore, & Costin, 1975).

Prediction 3 was that similarity manipulations, either alone or in conjunction with characteristics of the judges, would not affect ratings of functional role attraction. This prediction was based on the assumption that debates and discussions of controversial issues are by nature interesting and informative (i.e., reinforcing) to the extent that both sides of the issues are presented. In other words, ratings of another person's suitability to perform these roles should be based more on whether they have a point of view to express than whether they agree with us.

Preliminary Study

Scale Construction

The preliminary study was conducted to develop the Marital Role Decisions Questionnaire (MRDQ) that would be used in the main experiment to select individuals who had traditional or nontraditional orientations toward sex roles and marriage. Possible items for this questionnaire were initially elicited from 20 married couples who responded to an open-ended questionnaire that asked them to describe (a) "important decisions that you and your spouse (or couples you know) had to make where the two of you had opposing viewpoints" and (b) "the choices that were available to you and your spouse (or couples you know)."

This elicitation procedure produced nearly 40 possible items. These 40 items were then reduced to 14 by (a) eliminating trivial or idiosyncratic decisions, (b) discarding de-

Table 1
Comparison of Mean Scores on the Marital Role Decisions Questionnaire for Five Known Groups

Females		Males	
Group	Score	Group	Score
Members of NOW[a]	21.08$_a$		
College students	40.75$_b$	College students	43.92$_b$
Wives of policemen	51.00$_c$	Policemen	57.33$_c$

Note. Scores on the Marital Role Decisions Questionnaire could range from 12 to 84, with higher scores indicating a more traditional orientation toward sex roles and marriage. Means with different subscripts differ significantly from each other beyond the .05 level (two-tailed).
[a] National Organization of Women.

cisions thought not to be amenable to traditional and nontraditional responses, and (c) constructing composite descriptions of decisions that were similar in content. The 14 resulting decisions covered the areas of *domestic* (whether household chores should be shared), *financial* (whether home should be purchased or rented), *social* (whether functions should be attended separately or together), *familial* (whether children should be placed in a nursery), and *career* (who works to put whom through professional school) considerations. Except for domestic considerations, each content area was represented by 3 items. These decisions were then rewritten as dilemmas, each with a 7-point response format: slight, moderate, or strong agreement with a traditional or a nontraditional alternative for resolving the dilemma and a "cannot decide" response.

Reliability and Validity

To test the reliability and validity of the MRDQ, the 14-item scale was administered to a small number of individuals from five "known groups." The number of individuals and the five groups from which they came were 13 female members of a local chapter of the National Organization of Women (NOW); 12 female college students; 12 spouses of policemen; 13 male college students; and 12 policemen. It is important to note that these samples were independent. That is, the female and male college students were from different schools, and the spouses of policemen and the policemen were not married to one another.

Coefficient alpha was computed to determine the reliability of the MRDQ. With each item treated as a parallel measure, reliability for the 14-item MRDQ was .78. However, inspection of the data revealed that 2 items (1 social and 1 financial dilemma) functioned independently of the other 12 items. The deletion of those 2 items produced a 12-item MRDQ scale with a reliability of .79.

The validity of the 12-item MRDQ scale was assessed by determining whether the responses of the known groups significantly differed in the expected direction. The results of these comparisons are presented in Table 1. As can be seen there, the mean MRDQ scores for the three groups of women significantly differed from each other: The NOW women were more nontraditional than college women, who in turn were more nontraditional than the spouses of policemen. As Table 1 also indicates, the two groups of male respondents significantly differed from each other: Male college students were more nontraditional than policemen. Comparisons between the sexes for comparable groups revealed no significant differences, although female college students and the spouses of policemen were slightly more nontraditional than their male counterparts. In summary, then, the preliminary study showed that the 12-item MRDQ had sufficiently good psychometric properties for use as a research instrument.[1]

[1] Copies of the MRDQ, as well as instructions and scoring procedures for its use, are available from the first author upon request.

Main Experiment

Method

Design

The experiment had a 2 (female or male) × 2 (traditional or nontraditional) × 2 (similar or dissimilar) between-subjects factorial design. The first two factors involved characteristics of the experimental participants, who served as judges in an impression-formation task. The factor of traditionality was determined by participants' responses on the MRDQ. Individuals scoring above the true midpoint of the scale were classified as "traditionals," whereas individuals scoring below the true midpoint were classified as "nontraditionals." The third factor was whether the target person's score on the MRDQ was similar or dissimilar to the judge's score.

Participants

One hundred twenty-eight college students (64 females and 64 males) served as experimental participants, with 16 individuals participating in each cell of the 2 × 2 × 2 design.[2] All students were enrolled in introductory psychology courses at Northern Illinois University and received extra course credit for their voluntary participation in the experiment. Students were recruited during the first week of classes, at which time volunteers completed the MRDQ. The experiment was conducted several weeks later, with students participating in groups of 5 to 10.

Procedure

Under the guise of an impression-formation task, each student examined the MRDQ responses of an opposite-sex stranger. Consistent with the cover story, no other information about the strangers was given except that they were also college students and of the same age group as the participants. The strangers' responses on the MRDQ were manipulated to be either similar or dissimilar to the students' response patterns. After examining the strangers' MRDQ responses, the students recorded their impressions of the strangers on items intended to measure personal role, functional role, and general attraction. Finally, all students were thanked for their participation and debriefed about the general purpose and methodology of the investigation.

Similarity Manipulations

The target person's response pattern on the MRDQ was manipulated to be either 10 (similarity) or 30 (dissimilarity) points discrepant and opposite in direction from the student's response pattern. The rules for constructing the target's MRDQ responses were (a) always change the target's responses in the direction that is opposite the student's overall score on the MRDQ; (b) make three sequential changes of 10 points each; (c) for each sequential change, randomly alter as many different items as possible; and (d) avoid using the "cannot decide" response. Once these rules were employed, each student was randomly assigned to the similar or dissimilar condition. Similarity and dissimilarity were based on 10 and 30 points, respectively, because the standard deviation of scores on the MRDQ was 10.32 for this population.

Dependent Measures

The dependent measures included items intended to measure personal role, functional role, and general attraction. There were three items intended to measure personal role attraction, or the extent to which the judge would enjoy interacting with the target person: How suitable is the target person as a work, dating, and marriage partner? There were three items intended to measure functional role attraction, or the extent to which the judge would enjoy observing the target person perform public roles: How suitable is the target person as a debater, panelist, and discussant on sex roles and marriage? A single item measured how much the judge would generally like the target person. Four filler items assessed the degree to which the target person was intelligent, moral, socially adjusted, and knowledgeable about current affairs. All 11 items were assessed on 7-point response scales, with anchors of "very much" and "very little."

Results

Reliability

Item analysis based upon pooled within-cell correlations was used to assess whether items designed to measure personal and functional role attraction could be legitimately combined. Ratings of the target persons' suitability as work, dating, and marriage partners were highly intercorrelated with each other (mean $r = .65$). Scores on these items were thus averaged to create a measure of *personal role attraction*. Ratings of the target persons' suitability as debaters, panelists, and

---

[2] In actuality, two replications of the experiment were conducted during two consecutive semesters. Since an analysis for a replicated experiment produced no reliable differences between the two semesters, the data for both semesters were combined to increase the power of the subsequent analyses.

Table 2
Mean Ratings of Personal Role, General, and Functional Role Attraction for the Eight Experimental Groups

Experimental group	Attraction measure				
	Personal role		General		Functional role rating
	Rating	p	Rating	p	
Female–nontraditional					
Similar	5.50	<.001	5.19	<.01	5.19
Dissimilar	2.87		4.13		5.23
Female–traditional					
Similar	5.25	*ns*	5.31	*ns*	5.51
Dissimilar	5.46		5.13		6.19
Male–nontraditional					
Similar	5.08	*ns*	5.13	*ns*	5.04
Dissimilar	4.50		4.81		4.71
Male–traditional					
Similar	4.45	<.02	5.06	<.01	4.90
Dissimilar	3.54		3.88		5.27

Note. Ratings on each attraction measure could range from 1 to 7, with higher ratings indicating greater attraction. Given that there were four directional predictions concerning the simple tests, a conservative alpha level would be .0125 rather than .05.

discussants of sex roles and marriage were also highly intercorrelated (mean $r = .60$). Scores on these items were thus averaged to create a measure of *functional role attraction.* Since personal role items were only minimally correlated with functional role items (mean $r = .17$), discriminant evidence was also sufficient to treat these two sets of items as separate measures of attraction. Finally, the likability item was treated as a single measure of *general attraction,* because its mean correlations with personal and functional role attraction were .53 and .28, respectively.

Principal Hypothesis

The three attraction measures were treated as separate dependent variables in a multivariate analysis of variance. The results of this analysis showed that the multivariate F for the Sex × Traditionality × Similarity interaction was significant, $F(3, 118) = 4.42$, $p < .01$. The corresponding univariate Fs for personal role and general attraction were also significant: $F(1, 120) = 12.34$, $p < .001$, and $F(1, 120) = 5.73$, $p < .05$, respectively. The univariate F for functional role attraction was not significant, $F(1, 120) = .01$, $p > .90$. These findings supported the principal hypothesis that sex and traditionality of the judges would interact with similarity of the targets in determining personal role and general attraction but not functional role attraction.[3]

Specific Predictions

Simple tests compared the personal role and general attraction ratings of similar and dissimilar target persons made by the various judges. The results of these comparisons are reported in Table 2. As can be seen there, nontraditional females displayed a distinct

[3] As an alternative test of the principal hypothesis, a profile multivariate analysis of variance was conducted. This analysis included two linear combinations of the attraction measures: (a) the average of personal and general attraction versus functional attraction and (b) personal versus general attraction. The results of this analysis were statistically significant, $F(2, 119) = 4.94$, $p < .01$. A step-down analysis indicated that the first contrast accounted for a significant amount of variance in the overall analysis, $F(1, 120) = 9.44$, $p < .005$, whereas the addition of the second contrast did not, $F(1, 120) = .49$. Thus, the results of this analysis also supported the principal hypothesis.

preference for similar as opposed to dissimilar target persons on personal role and general attraction ($p < .001$ and $p < .01$, respectively). Traditional men also preferred similar partners on personal role and general attraction ($p < .02$ and $p < .01$, respectively). By contrast, traditional women and nontraditional men displayed no such preference for similarity on either attraction measure ($ps > .15$). These findings supported Predictions 1 and 2 of the principal hypothesis.

Although Table 2 contains the means for functional role attraction, simple tests were not conducted because they were unwarranted. As already noted, for example, the triple interaction for functional role attraction was not significant. Moreover, the main effect for similarity was not significant, $F(1, 120) = .97$, $p > .30$. The Sex × Similarity and the Traditionality × Similarity interactions were also nonsignificant: $F(1, 120) = .77$, $p > .35$, and $F(1, 120) = 3.07$, $p > .08$, respectively. These findings supported Prediction 3 of the principal hypothesis.

Discussion

This study tested the hypothesis that role and dispositional factors can moderate the effects of similarity on attraction. Results showed that nontraditional women and traditional men displayed more liking (general attraction) and stronger preferences for similar versus dissimilar others as work, dating, and marriage partners (personal role attraction). By contrast, traditional women and nontraditional men were equally attracted to similar and dissimilar others on these same measures. Results also showed that all judges considered similar and dissimilar others to be equally suited to perform the roles of debaters, discussants, and panelists on topics of sex roles and marriage (functional role attraction). In summary, this study demonstrated that characteristics of judges and dimensions of judgment can affect interpersonal attraction as much as similarity of target persons.

The significance of the present study lies in the fact that it is apparently the first to produce clearly replicated results (see Footnote 2) of the moderating effects of dispositional factors on attraction responses.[4] Thus, the question naturally arises as to why the present study succeeded when past efforts have generally failed in this regard (see Byrne, 1971; Fishbein & Ajzen, 1972).

One possibility is that previous studies typically used Byrne's Interpersonal Judgment Scale (IJS), whereas the present study employed different attraction measures. Since the likability and work partner items of the present study are psychologically similar to the two items comprising the IJS, an analysis of these combined items was conducted to test this possibility. Not surprisingly, the results of this analysis were exactly parallel to those for personal role and general attraction: The Sex × Traditionality × Similarity interaction was significant, $F(1, 120) = 13.80$, $p < .001$; nontraditional women displayed a distinct preference for similarity, $F(1, 30) = 33.05$, $p < .001$, as did traditional men, $F(1, 30) = 7.19$, $p < .05$; and traditional women and nontraditional men displayed no such preference ($Fs < 1.50$). Thus, the success of the present study cannot be attributed to its use of a novel measure of attraction.

A second possibility is that previous studies failed to obtain moderating effects because the relationship between dispositional factors and similarity manipulations was more tenuous than in the present study. For example, in the studies of authoritarianism, participants' scores on the *F* scale and their responses on the attitude items were either unrelated (Byrne, 1965) or only minimally correlated (Sheffield & Byrne, 1967). Thus, it is not surprising that authoritarianism did not interact with the similarity of others' responses on issues that were generally unrelated to the authoritarian ideology. In other

---

[4] Although moderating effects on attraction have been obtained with need for affiliation, different investigations have produced different results (cf. Byrne, 1961, 1962). Somewhat similarly, the dispositional variable of social avoidance and distress has significantly interacted with similarity in affecting attraction in one study (Smith, 1972) but not another (Gouaux, Lamberth, & Friedrich, 1972).

studies, the tenuous relationship may have occurred in terms of unrealistic expectations about the personal benefits of attitude similarity. For example, it seems unreasonable to expect that individuals with high need for approval (Ettinger, Nowicki, & Nelson, 1970) can be so positively affected by attitude similarity that they will display more attraction toward agreeing strangers than that displayed by individuals with low need for approval.

By contrast, the present study ensured a close relationship between dispositional variables and similarity manipulations by using the same items to assess the dispositional variable and to manipulate similarity. Furthermore, information contained in these items was directly relevant to the dependent measures of attraction. For example, faced with the task of rating a target person's suitability as a potential marriage partner, participants could directly assess whether their own orientations toward marriage were compatible with the target person's orientation. Thus, the present study was probably successful in finding interactions because there was a closer correspondence between dispositional factors and similarity manipulations than that which existed in previous studies.

Alternative Interpretations

While the present findings were predicted from a reinforcement perspective, they are compatible with informational approaches to attraction. For example, Ajzen (1974) views attraction as being a summed function of the subjective probabilities that a target person has certain attributes and the affective values of those attributes. Thus, if nontraditional women and traditional men consider similar others to have more positive attributes for personal roles than dissimilar others, they would evaluate similar others more positively than dissimilar others. If these same judges also consider both similar and dissimilar others to have equally positive attributes for functional roles, they would evaluate both target persons equally well.

The present findings are also compatible with Kaplan and Anderson's (1973) information integration approach to attraction. According to this approach, variations in the judges' initial impressions or in the scale values and weights assigned to pieces of information about the target persons could account for the results obtained here. For example, the personal role findings could be due to nontraditional women and traditional men having more negative initial impressions of dissimilar others than traditional women and nontraditional men have of them. Additionally, differences between personal and functional role findings could be due to differences in the scale values or weights assigned to the same target when that person is judged on different dimensions.

A final interpretation warrants comment. The similarity manipulations of this study bear a strong resemblance to discrepancy manipulations in persuasion research. Thus, if nontraditional women and traditional men held extreme views on marriage, their dislike of dissimilar others would merely replicate the well-known derogation effect of discrepant communications and communicators (Hovland, Harvey, & Sherif, 1957; Johnson, 1966). To determine whether any group of judges held extreme views on marriage, mean MRDQ scores were computed for each group. The mean scores of both groups of nontraditional women were nearly two standard deviations away from the midpoint of the scale. However, the mean scores of all other groups, including the two groups of traditional men, were within a standard deviation of the midpoint.

Thus, extremity and discrepancy may account for the nontraditional women's dislike of dissimilar others on personal role and general attraction. However, these factors cannot explain the traditional men's derogation of dissimilar others on these same measures. Nor can they explain the nontraditional women's liking of dissimilar others on functional role attraction. This latter point is particularly important because functional attraction assessed the target persons' suitability to perform roles (e.g., debater) that are similar to the communicator roles for which derogation effects have been obtained. In summary, extremity and discrepancy may account for part of the present findings but not their overall pattern.

Conclusion

McGuire (1968) has argued that the principles governing human affairs are more likely to be contingent-interactive effects rather than condition-free main effects. In this regard, the present study represents a modest beginning in the area of interpersonal attraction. That is, the present study demonstrated that interpersonal attraction can be a multivariate function of the type of person making the judgment, the type of person being judged, and the type of dimension upon which the judgment is made. As investigators continue to pursue the interactive nature of interpersonal attraction more fully, it is hoped that the principles underlying evaluative judgments of others will begin to emerge more explicitly.

Simple Minitheories of Love

P. M. Bentler and G. J. Huba
University of California, Los Angeles

Two causal models of love were developed as alternatives to the Tesser and Paulhus theory. These models were tested for adequacy of fit using maximum-likelihood methods. While the Tesser–Paulhus models can be rejected empirically, the alternate models provide acceptable statistical representations of four variables measuring love at two times separated by 2 weeks. One formulation is based on the idea of unidimensionality of interpersonal attraction. The second formulation represents a refinement of the Tesser–Paulhus view of love. The formulation based on the idea that interpersonal attraction is primarily a unidimensional construct provides the more parsimonious and interpretable theory.

Causal modeling methods have been used in this journal to evaluate a theory of love (Tesser & Paulhus, 1976). As a method of theory testing with correlational data, causal modeling represents a set of statistical techniques for investigating sample data in the light of hypothesized population models of the influence of certain variables on others. In general, a model represents a simultaneous series of statements about the regression of particular variables on various other ("causal," explanatory) variables. The most popular form of causal modeling, path analysis, is thus a sophisticated form of simultaneous multiple correlation/regression analysis, while recent developments in causal modeling embed path analysis into a factor-analytic type of framework. In such a framework, the regressions are at the level of the unmeasured, latent variables or factors, and the factors themselves are related by factor-analytic assumptions to the observed, manifest variables in the system. The goals of causal modeling include both the testing of a proposed model against data and the development of models that adequately account for data. The interrelations among causal modeling, data analysis, theory testing, and construct validation have been discussed by Bentler (1978).

Although causal models must be evaluated by a variety of criteria including meaningfulness, they can be tested statistically via the chi-square statistic: The hypothesis that the sample variances and covariances are drawn from a population having a hypothesized causal structure is tested against the alternative hypothesis that the variables are simply correlated. If the chi-square is large relative to degrees of freedom, the proposed causal structure must be rejected, because the observed sample data would be extremely unlikely to be obtained if the hypothesized model were true in the population. The chi-square statistic, in turn, is developed on the basis of various mathematical and statistical assumptions. A very general mathematical system of equations for causal models (Bentler, 1976) reduces to a set of equations described by Wiley (1973) and Jöreskog (1977), for which a computer program, LISREL III, exists, to obtain maximum-likelihood estimates of model parameters and chi-square statistics (Jöreskog & Sörbom, 1976). For a proof of these relations, see Bentler & Woodward (1978); for a more general model and computer program, see Weeks (1978). In this article, we use these recent approaches to reevaluate Tesser and Paulhus's theory and to evaluate two new minitheories of love.

Tesser and Paulhus (1976, p. 1099) ob-

The authors wish to thank Abraham Tesser for helpful comments on the manuscript.

tained the variances and covariances among four measures associated with the concept of love, assessed for 202 subjects on two occasions separated by 2 weeks. The first variable indicates how often the participant *thought* about a target love person during the previous 2 weeks (T_1 and T_2, where "1" and "2" indicate the measurement occasion). *Love* (L_1 and L_2) was assessed by Rubin's (1970) nine-item love scale. *Reality constraints* (RC_1 and RC_2) were assessed via a scale of new information obtained about the target person that confirmed (high RC) or contradicted (low RC) expectations. Finally, *dating* (D_1 and D_2) was indexed by the subject's report of number of dates with the target person during the previous 2 weeks. Any proposed miniature theory should account for the variances and covariances among variables on both occasions in a statistically acceptable manner; the means of the variables are irrelevant to the causal modeling formulation.

Tesser and Paulhus developed two causal models for their data. In these models, all variables on the first measurement occasion are allowed to correlate freely, and certain variables at the second occasion are functions of particular first-occasion variables, some simultaneous Occasion 2 influences, and residual or unknown effects. The details of the Tesser–Paulhus (1976) original model (p. 1098) and the final model (p. 1100) need not be described here, since, unfortunately, the Tesser–Paulhus models do not fully fit their data. Although Tesser and Paulhus (1976, 1978) apparently believe that a successful model has been developed to fully describe the measures and the 36 variances and covariances, the models only fit 28 of the dispersions, and arguments about the meaning of the models (Smith, 1978; Tesser & Paulhus, 1978) are limited to the subset of relationships. It can be shown that the original model, fit to all the data, yields as an index of fit a χ^2 value of 25.2, with 9 degrees of freedom, indicating that the sample covariance matrix is extremely unlikely ($p = .003$) to be drawn from a population having the proposed causal structure. Although Tesser and Paulhus's final model is reasonable for 28 of the 36 variances and covariances (i.e., by excluding reality constraints on the second testing), it is not capable of explaining all the data. When reality constraints on the second occasion are included, one obtains a χ^2 of 55.6, with 14 degrees of freedom ($p < .0001$), thus requiring similar rejection of the final model.[1]

Since the Tesser–Paulhus theory is not consistent with the data, one may inquire whether any other theory could be developed that would be successful in describing their data. Such a theory should properly be based on prior psychological theorizing. The purpose of this note is to explore two alternative miniature theories of love, based on research in interpersonal attraction, and to test these models in the Tesser–Paulhus data using maximum-likelihood estimation and chi-square goodness-of-fit tests. The first formulation is based on the well-known idea of unidimensionality of interpersonal attraction, whereas the second approach is a refinement of the Tesser–Paulhus view of love. Both formulations will be shown to be capable of explaining all the data involved.

A Unidimensional, Latent-Variable Approach to Love

Interpersonal attraction is often defined as "attitudinal positivity" (Huston & Levinger, 1978), which implies a general construct of favorability–unfavorability towards a partner. Consequently, it is not surprising that "most researchers have assumed that attraction is a unidimensional variable" (Berscheid & Walster, 1978, p. 3). As a consequence, one possible model for the Tesser–Paulhus love data would propose that the four variables being measured represent indicators of generalized love and attraction

[1] It should be noted that the general mathematical models and computer programs for their implementation were not widely distributed at the time Tesser and Paulhus did their research. Given the theoretical formulations and software available at the time, the Tesser–Paulhus solution of deleting one variable was quite appropriate, and their model fits the data within that context. Newer methodology, however, makes it possible to develop a more complete and robust model for these data.

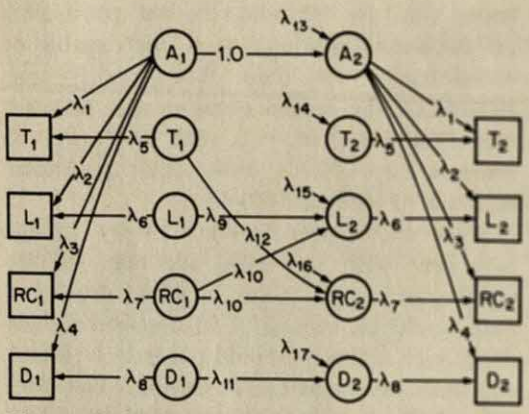

Figure 1. Schematic representation of a simple latent-variable (λ) model linking general attraction (A), love (L), thought (T), reality constraints (RC), and dating (D) at two different times (1 and 2).

toward a partner. Unfortunately, such a model was never evaluated for the Tesser–Paulhus data. In such a model, one would suppose that all of the observed variables are reflections of a single latent construct (a "common factor") of attraction (A) towards the target person. Additionally, it seems reasonable to posit that each of the variables also measures its own special quality or attribute (a "unique factor"), so that one can propose that the four overt variables on the first occasion represent the five latent variables of general attraction, A_1, and the specific attributes T_1, L_1, RC_1, and D_1. That is, each observed variable is composed of, or in part attributable to, general attraction and uncorrelated specific influences including measurement error. Since the times of measurement were separated by the short period of 2 weeks, the most simple unidimensional model of these love measures would additionally propose that the identical measurement structure exists on the second occasion (i.e., the loadings of the four variables on the common and unique factors are the same at both times). Furthermore, the most parsimonious way of interrelating the measures across time is to posit a simple reliability model, in which the second-occasion constructs are linear functions of only the associated first-occasion construct plus a residual. Thus, for example, $T_2 = wT_1 + e$, where w is a weight and e is a residual (i.e., the unique part of thinking about an individual at the second time is adequately predicted by regressing it only on the unique part of thinking about the individual at the earlier time). This particular latent-variable model does not adequately fit the data, $\chi^2(18) = 40.5$, $p < .002$, thus lending some credence to the Berscheid-Walster (1978) criticisms of simple unidimensionality. However, some slight modifications of this specialized model, constraining the parameters of measurement structure to be identical, does yield a formulation based on the unidimensionality of attraction that adequately fits all the observed variances and covariances.

Figure 1 presents the modified unidimensional reliability model. Since it yields a nonsignificant goodness-of-fit index, $\chi^2(19) = 24.2$, $p = .19$, one can conclude that the observed sample data are consistent with the population model shown. The estimates for the model parameters, their standard errors, and critical ratios (formed by dividing the parmeter estimates, minus the null value of zero, by the respective standard errors) are shown in Table 1.

Table 1
Latent-Variable Model Parameter Estimates, Standard Errors, and Critical Ratios (CR)

Parameter	Estimate	*SE*	CR
	Within-occasion parameters		
λ_1	3.18	.18	17.29
λ_2	16.16	1.10	14.68
λ_3	.29	.10	3.06
λ_4	1.52	.18	8.37
λ_5	1.83	.14	13.35
λ_6	10.31	.71	14.53
λ_7	1.77	.09	20.09
λ_8	2.48	.13	19.21
	Cross-time parameters		
λ_9	.70	.08	8.21
λ_{10}	.20	.05	4.08
λ_{11}	.80	.05	15.33
λ_{12}	−.28	.08	−3.49
	Residual parameters		
λ_{13}	.17	.04	4.07
λ_{14}	.55	.16	3.35
λ_{15}	.79	.14	5.45
λ_{16}	.80	.12	6.87
λ_{17}	.48	.07	6.74

The figure uses a convention, now quite standard in the methodological literature, of representing observed variables by squares. The latent constructs, which are unmeasured, are represented in circles. The entire minitheory proposes directional causal influences, with the causal flow originating in the latent variables and yielding the overt variables (the measurement model) as well as cross-time effects on the latent variables (the structural model). The coefficients λ_i represent the parameters of the model to be estimated (the estimates are given in Table 1). It can be seen that at both occasions, there are five latent constructs, the specific constructs associated with each variable (e.g., T_1) and the general attraction construct, A_1. The parameters of the measurement structure, λ_1 to λ_8, are constrained to be identical on both occasions. The cross-time causal effects are given by parameters λ_9 to λ_{12} (with the two λ_{10} parameters set equal), while λ_{13} to λ_{17} represent regression residuals (i.e., the unpredictable parts of the Time 2 latent constructs). The specific estimated values for the parameters, as reported in Table 1, can be used to reproduce the data to within statistical accuracy. However, the important feature of Table 1 lies in the critical ratios (CR), which are like familiar z ratios, each representing a ratio of the parameter estimate minus the null value of zero to its standard error. Using most familiar cutoff values for this ratio shows that all parameters are important to the model.

The substantive meaning of the simple model in Figure 1 is the following: The general attraction construct on the second occasion, A_2, is caused by a simple weighted sum of general attraction (A_1) and a residual (λ_{13}). That is, general attraction is stable over a 2-week period and is not altered by specific aspects of thought, love, reality constraints, or dating. Each specific construct on the second occasion is given by a weighted sum of the identical construct on the previous occasion plus a residual (e.g., $L_2 = \lambda_9 L_1 + \lambda_{15}$). Thus, each of the specific parts of the measured variables is stable across 2 weeks. The single exception is given by thought on the second occasion (T_2), which is independent of a causal influence of thought at the initial time (T_1); apparently, the specific aspect of thoughts (T_2) cannot be predicted from any variable or construct at initial testing. Finally, there are two cross-variable causal influences across time, with T_1 affecting RC_2 and RC_1 influencing L_2. The meaning of these influences appears to be that the more subjects think about their dates at Time 1, the *more* they subsequently believe that recent, new information about their friend contradicts their expectations; and the more they initially believe that information about their friend confirms expectations, the more they tend to love their friend later.

It is possible that the first cross-variable effect reflects an unrealistic quality associated with excessive initial brooding, which becomes contradicted with real, intervening experience, and that the second cross-variable effect reflects the loving consequences of early cognitive security. While the last two links were necessitated by the data and not postulated in the simple reliability model, the affective consequences of having expectations validated seem consistent with the laboratory studies cited by Clore and Byrne (1977) and are well justified by Tesser and Paulhus (1976). Furthermore, the link between large amounts of initial thought about the partner and believing that new information contradicts expectations reflects a point that is made by Tesser and Paulhus in their original article (1976, p. 1095) in citing Kerckhoff and Davis (1962), who note that a "point so often stressed in the literature is that couples go through a period of idealization and perception distortion which may lead to disillusionment (or 'reality shock') at a later date" (p. 302). It must be remembered, furthermore, that the cross-time links are between those parts of the variables *not* attributable to general attraction or evaluation; within this context, both links seem quite interpretable. Of course, these explanations associated with the model must await testing with further data in the context of a larger causal model including measures of the hypothesized influences. Although our statistical methods are reassuring regarding the internal validity of the model, external validity or generalizability to

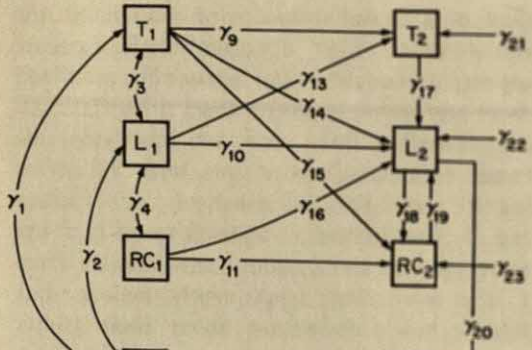

Figure 2. Schematic representation of a simple manifest-variable (γ) model linking love (L), thought (T), reality constraints (RC), and dating (D) at two different times (1 and 2).

other situations must await further research. Smith (1978) has made a similar point.

A Manifest-Variable Approach to Love

Although the above model based on general attraction is a viable one, it is also possible that a model without such a construct may fit the data. Among such models, the simplest one is surely a reliability model for the variables across time. This model proposes that the four variables at Time 1 could be freely intercorrelated but that all causation across time consists of simple links such that a given variable depends causally only on its predecessor (e.g., $T_2 = wT_1 + e$). As might be expected from the previous result, this simultaneous regression model for the four observed, manifest variables measured on two occasions also could not account for all features of the data, $\chi^2(18) = 139.7$, $p < .0001$. Cross-variable causation is obviously essential to enable the model to fit the data, and thus a 24-parameter model was developed that would contain the features of the simple model, while incorporating some of the most necessary causal influences proposed by Tesser and Paulhus. This model is presented in Figure 2, and the parameter estimates, standard errors, and critical ratios are given in Table 2. This model, when estimated by maximum likelihood, has an acceptable index of fit, $\chi^2(12) = 15.9$, $p = .20$. Thus, although the manifest-variable model has 24 parameters as compared to the previous latent-variable model with 17 parameters, the manifest-variable model also cannot be *statistically* rejected for these data.

The manifest-variable model can be considered to be in the spirit of the Tesser–Paulhus approach. It considers the variables at Time 1 to be exogenous (noncausal) variables, with parameters γ_1 to γ_4 associated with covariances among the variables and γ_5 to γ_8 with their variances (not shown in the figure, but given in the table). Unlike the Tesser–Paulhus model, however, the current model found that the estimated covariances of T_1 and RC_1 and of RC_1 and D_1 could be

γ_{23}	2.84	.30	9.51
γ_{24}	3.12	.31	10.02

set to zero, so that no parameters are needed for these covariances. (Stated differently, the observed correlations of .129 and .086 could not be considered to be significantly different from 0.) The causal connections across time again required consideration of effects of specific variables on themselves (γ_9 to γ_{12}) as well as some cross-variable effects (γ_{13} to γ_{16}). Two such effects, associated with γ_{15} and γ_{16}, were described in the context of the previous model and would seem to have a similar interpretation in the current model. The remaining effects seem to indicate that loving leads to thinking about one's loved one (γ_{13}) and that extensive thinking at Time 1 leads to *reduced* loving at Time 2. It is as if thinking does not have a positive effect on loving at a later time; but this hypothesis is contraindicated by the endogenous, within-Time-2 effect represented by γ_{17}, which is positive. The remaining endogenous effects, γ_{18} to γ_{20}, are not consistent with the Tesser and Paulhus concept of retrospective assessment on T, RC, and D, which they suggested would cause love, a contemporaneously measured variable. Rather, we find L_2 having an effect on RC_2 (γ_{18}) and on D_2 (γ_{20}), in addition to the effect of RC_2 on L_2 (γ_{19}). These causal paths, though statistically necessary to the model, do not appear to us to be particularly interpretable. Finally, the parameters γ_{21} to γ_{24} reflect the residuals of the causal model.

Discussion

Although we have developed a path analysis model at the level of the manifest variables that would indeed account for the observed data reported by Tesser and Paulhus, we agree with Smith (1978) that causal models of love should not be formulated at the level of overt variables. Not only is the model of Figure 2 likely to be modified solely as a consequence of arbitrary changes in the reliability of the variables involved, but considering all variables at Time 1 as exogenous and outside the explanatory system seems to be shortsighted. The unidimensional latent-variable model not only accounts for the overt variables at Time 1, it also provides for a very simple representation of effects across time and does not require complicated reciprocal causation among variables at Time 2. Since the latent-variable model provides an accurate description of the data with seven fewer parameters, parsimony also favors the latent-variable model. Furthermore, this latent-variable model is consistent with many research approaches to interpersonal attraction as a unidimensional construct (cf. Huston, 1974). Finally, although the manifest-variable model is *statistically* acceptable for the data, there are clear theoretical ambiguities that make this formulation of dubious validity. For example, the opposing signs associated with the effects of thought on love (γ_{14} vs. γ_{17}) are not consistent with the observed positive intercorrelations among all four thought and love variables. While the correlation between thought at Time 1 and love at Time 2 is .612, the associated regression weight is -1.09, suggesting an uninterpretable suppressor effect.

A glance at Figures 1 and 2 will provide rapid visual evidence for the dissimilarities among the models, but certain similarities should also be observed. In particular, both models propose an effect for a given variable on itself across time. In the manifest-variable model, all these effects are important, while in the latent-variable model all but the reliability of the *specific* parts of thought (T_1 and T_2) are necessary. The two cross-variable paths (λ_{12} vs. γ_{15} and λ_{10} vs. γ_{16}) have also been noted and discussed previously. Since these effects appear to be similar across two completely different formulations of the phenomenon, it is likely that they represent fundamental features of the experience of love.

In contrast to the original models of Tesser and Paulhus (1976), which were debated by Smith (1978) and Tesser and Paulhus (1978), the current formulations are consistent with all the data collected. While we do share the concerns of Smith (1978) that causal modeling should be theory based and a priori, the unidimensional model we have presented is consistent with current psychological formulations of general interpersonal attraction as operationalized in existing laboratories around the country, as well as being a slight modifi-

cation of the most mathematically simple model for the data. Of course, it must be recognized that in moderately sized samples such as the present one, minor modifications can be made in the present models that would yield indexes of fit approximately comparable to those we have obtained; such modifications should, however, incorporate all the measurement and structural influences found to be necessary here.

Since causal models of nonexperimental data can be modified substantially when other crucial causal influences are simultaneously considered, the current models must not be considered as final theoretical formulations of love, but rather as potentially interesting representations of the Tesser–Paulhus data.[2] As additional longitudinal data are collected about love, it should prove useful to include the present models as a subset of some larger, more comprehensive formulation in order to account for changes over time in attraction and emotional responses to significant others, and to attempt to reject the proposed simple model in explaining comprehensively the phenomena of interpersonal attraction and love.

[2] Unfortunately, the sample of Tesser and Paulhus is too small to allow a cross-validation study of the models.

Statistically Combining Independent Studies: A Meta-Analysis of Sex Differences in Conformity Research

Harris M. Cooper
University of Missouri—Columbia

Traditional (literary) reviews of research in social psychology are compared with a statistical approach. It is concluded on both abstract and practical grounds that adoption of the statistical approach would lead to theoretical progress for the research area covered. A meta-analysis "package" is described and then applied to the question of whether there are sex differences in degree of conformity. The meta-analysis is yoked to a literary analysis, and conclusions of differing direction and confidence appear. Problems in application are encountered, and appropriate courses of action are discussed. Finally, limitations on the power of the procedure are outlined.

The traditional way to review research in social psychology has been to take a literary approach. That is, summary statements about research areas are usually based on impressions gleaned by the reviewer from a reading of related studies. This article takes issue with the efficiency of such an approach. An example of a *statistical* technique for combining the results of independent experiments is provided, and this approach is contrasted with a literary summary. The quantitative procedures describe numerically the characteristics of a body of evidence and give a probability level related to the observed pattern of results. Although the actual numerical manipulations require little statistical sophistication, the theoretical progress possible through their employment may be great (progress is here defined as more precise and confident statements about segments of our world). The reasons for believing that progress will follow the adoption of quantitative procedures are both abstract and practical. The abstract reasons are presented first, and the practical reasons are given after the illustration is in hand.

Theoretical progress within a scientific discipline is intimately tied to two other kinds of advancement, one relating to methodology and the other relating to the volume of research being produced. Methodologically, advancement can occur in either research design or analysis, but both advancements typically involve the development of increasingly precise measurement instruments. In the case of design refinements, precision of measurement permits the observation of events that were inaccessible before. An example of this kind of advancement would be, say, the introduction of videotape to the study of nonverbal behavior. Analysis refinements, on the other hand, allow for the more exact description of observed phenomena. Such an advance would be the development of factorial analysis of variance. Factorial designs allow researchers to reduce error (in comparison to one-way designs) and to study interaction. An increased ability to define a concept operationally, to measure it soundly and powerfully, and to study it in relation to other concepts will clearly influence related theoretical developments.

The second kind of advance related to theoretical progress is the accumulation of

cation of the most mathematically simple model for the data. Of course, it must be recognized that in moderately sized samples such as the present one, minor modifications can be made in the present models that would yield indexes of fit approximately comparable to those we have obtained; such modifications should, however, incorporate all the measurement and structural influences found to be necessary here.

Since causal models of nonexperimental data can be modified substantially when other crucial causal influences are simultaneously considered, the current models must not be considered as final theoretical formulations of love, but rather as potentially interesting representations of the Tesser–Paulhus data.[2] As additional longitudinal data are collected about love, it should prove useful to include the present models as a subset of some larger, more comprehensive formulation in order to account for changes over time in attraction and emotional responses to significant others, and to attempt to reject the proposed simple model in explaining comprehensively the phenomena of interpersonal attraction and love.

[2] Unfortunately, the sample of Tesser and Paulhus is too small to allow a cross-validation study of the models.

Statistically Combining Independent Studies: A Meta-Analysis of Sex Differences in Conformity Research

Harris M. Cooper
University of Missouri—Columbia

Traditional (literary) reviews of research in social psychology are compared with a statistical approach. It is concluded on both abstract and practical grounds that adoption of the statistical approach would lead to theoretical progress for the research area covered. A meta-analysis "package" is described and then applied to the question of whether there are sex differences in degree of conformity. The meta-analysis is yoked to a literary analysis, and conclusions of differing direction and confidence appear. Problems in application are encountered, and appropriate courses of action are discussed. Finally, limitations on the power of the procedure are outlined.

The traditional way to review research in social psychology has been to take a literary approach. That is, summary statements about research areas are usually based on impressions gleaned by the reviewer from a reading of related studies. This article takes issue with the efficiency of such an approach. An example of a *statistical* technique for combining the results of independent experiments is provided, and this approach is contrasted with a literary summary. The quantitative procedures describe numerically the characteristics of a body of evidence and give a probability level related to the observed pattern of results. Although the actual numerical manipulations require little statistical sophistication, the theoretical progress possible through their employment may be great (progress is here defined as more precise and confident statements about segments of our world). The reasons for believing that progress will follow the adoption of quantitative procedures are both abstract and practical. The abstract reasons are presented first, and the practical reasons are given after the illustration is in hand.

Theoretical progress within a scientific discipline is intimately tied to two other kinds of advancement, one relating to methodology and the other relating to the volume of research being produced. Methodologically, advancement can occur in either research design or analysis, but both advancements typically involve the development of increasingly precise measurement instruments. In the case of design refinements, precision of measurement permits the observation of events that were inaccessible before. An example of this kind of advancement would be, say, the introduction of videotape to the study of nonverbal behavior. Analysis refinements, on the other hand, allow for the more exact description of observed phenomena. Such an advance would be the development of factorial analysis of variance. Factorial designs allow researchers to reduce error (in comparison to one-way designs) and to study interaction. An increased ability to define a concept operationally, to measure it soundly and powerfully, and to study it in relation to other concepts will clearly influence related theoretical developments.

The second kind of advance related to theoretical progress is the accumulation of

evidence concerning a specific topic. Repeated observation allows for greater confidence in uncovered relations, when observations show consistent or similar results. Repeated results also increase confidence in the generalizability of observed phenomena, with intended and unintended differences in replications testifying to the robustness of relations. Statements that can be made with great confidence undoubtedly motivate future research to take a more precise theoretical tack. Methodological and accumulation advances are connected, in that increased precision of measurement reduces the number of observations necessary for relations to be accepted at a given level of confidence. In sum, then, it can be argued that refined measurements and the accumulation of aligned studies are two major spurs to theoretical progress.

With these relations in mind, one can argue that the traditional literature review in social psychology lacks analytic precision in at least three ways. First, literary reviews may be more susceptible to the idiosyncracies of a particular reviewer's perspective than are reviews using consensually validated statistical procedures. As Gene Glass (1976) states:

> A common method for integrating several studies with inconsistent findings is to carp on the design or analysis deficiencies of all but a few studies—those remaining frequently being one's own work or that of one's students or friends—and then advance the one or two "acceptable" studies as the truth of the matter. (p. 4)

Second, the literary review usually ignores the issue of relationship strength by rarely assessing the size of the effect under study. Lastly, the typical review imprecisely weights conclusions with respect to the volume of available evidence (Light & Smith, 1971).

It seems, then, that replacing the present literary model of research view with a statistical model would almost necessarily increase measurement precision. In addition, this particular replacement relates directly to the issue of accumulating evidence. Areas having statistical combinations, therefore, should benefit theoretically from the more exact description, sounder inferences, and greater confidence in observed phenomena that such a technique allows. Again to quote Glass (1976), statistical analysis "connotes a rigorous alternative to the casual, narrative discussions of research studies which typify our attempts to make sense of the rapidly expanding research literature" (p. 3).

A methodological advance cannot occur unless the development of a field is compatible with it. Many areas of social psychology are, I feel, compatible with the advancement proposed here. This judgment is based on two observations. First, certain areas have generated enough research on identical or conceptually similar topics that statistical procedures can be reliably applied to them. Many areas in social psychology can now cite 20, 40, or more similar hypothesis tests, as the example to be presented here illustrates. These areas seem "ready" for more precision. A second reason for the proposed compatibility between field and method is an increasing awareness concerning the importance of legitimate data analysis. Partially in response to McGuire's (1973) call for redirection, social psychology training programs tend now to require advanced course work in statistical procedures (I am myself a product of this "trend"). In addition, the major journals in the field increasingly present research analyzed with complex statistical techniques. While the procedures presented here require only a knowledge of the fundamental probability axioms behind nearly all published analyses, this increased exposure to statistics may remove some of the "inertia" that typically surrounds a newly introduced analytic procedure.

The term *newly introduced* was used above because the methods presented do not make their debut in this article. Before turning to the procedures themselves, however, let me summarize the arguments for their adoption. First, it has been noted that measurement advances and aligned research efforts can be expected to lead to theoretical progress. Second, within social psychology, more precise methodologies are available than the method presently used for drawing inferences from multiple tests of related hypotheses. Social theory, therefore, may benefit if these more precise analytic techniques are employed more frequently. Certain areas may be

"ready" for such precision because the volume of research available permits statistical testing and because researchers may now feel quite positive toward rigorous analytic procedures.

Meta-Analytics

Glass (1976) has suggested that data analysis can be categorized into three distinct activities: primary, secondary, and meta-analysis. *Primary* analysis occurs when the data of a given study are analyzed for the first time. *Secondary* analysis is the reanalysis of data. This may occur so that more appropriate statistical procedures can be applied or so that new questions can be answered with an old data set. Finally, *meta-analysis* occurs when the results of independent experiments are combined "for the purpose of integrating the findings" (p. 3).

Methods for meta-analysis have a history as long as most commonly used statistical procedures. In 1938, Fisher and Pearson both presented methods for obtaining an overall probability for a series of studies (Fisher, 1938, pp. 104–106; Pearson, 1938). In social psychology, Mosteller and Bush (1954) presented a meta-analysis procedure in the *Handbook of Social Psychology*. While early instances of meta-analysis applications are rare, they now appear with some frequency. Rosenthal (1976, p. 441) presents a meta-analysis testing the influence of interpersonal expectations on behavior. Over 300 studies are included. He reports that nearly 50,000 failures to find an influence would be needed to reverse, at the .05 level of significance, the conclusion that expectations affect behavior. Glass (1976) cites meta-analyses relating to teaching methods, television instruction, and socioeconomic status relations to IQ, to name a few. Smith and Glass (1977) present a meta-analysis integrating the literature on the outcomes of psychotherapy. Their conclusion, based on 375 studies, is that "therapy of any type under . . . average conditions can be expected to move the typical client from the 50th to the 75th percentile of the untreated population" (Glass, 1976, p. 7). Glass also concludes that these studies exhibit only a "trivial" advantage for behavioral over nonbehavioral therapies.

As the above examples illustrate, a meta-analysis is conducted on a group of studies related either because (a) they share a common conceptual hypothesis or (b) they share operations for the realization of the independent or dependent variables, regardless of conceptual focus. Meta-analytics result in a single set of numbers describing the body of literature involved. Typically, a significance level is generated, which addresses the question "What is the probability that a set of studies exhibiting these results could have been generated if no actual relation existed?" Other statistics are usually presented also, such as Rosenthal's assessment of the number of studies needed to reverse a conclusion and Glass's description of the percentile relation between experimental groups.

Meta-analytic procedures have been developed that range in sensitivity. The least sensitive test simply "counts" the number of probability levels below .50 (chance for the predicted direction) and asks whether this number is too large. The most sensitive procedures require that the raw data from included experiments be available (Light & Smith, 1971). Rosenthal (1978) has presented a detailed description of available meta-analytic methods, including their relative advantages and limitations. This effort will not be repeated here. The method to be illustrated presently asks only that probability levels from included studies be available. These levels are first transformed to Z scores (standard normal deviates) and then related to the number of studies involved. This procedure is presented because it is more precise than the counting method and more accessible than methods using raw data. In addition, the illustrated method requires no assumptions concerning data beyond those typically made by the authors of the original studies (i.e., linearity, normality, homogeneity of variance, independence of events) and requires that each study exhibit unit variance. The method was introduced by Stouffer in 1949 and then modified by Mosteller and Bush in 1954.

The weighted and unweighted Stouffer

method. The Stouffer (1949, p. 45) method for combining studies uses the following formula:

$$Z_{ma} = \frac{Z_{s1} + Z_{s2} + \cdots Z_{sn}}{\sqrt{N_s}}, \qquad (1)$$

where Z_{ma} = the standard normal deviate for the meta-analysis; $Z_{s1} \cdots Z_{sn}$ = the standard normal deviate for each included study; and N_s = the total number of studies included. The method asks that the reviewer take the following steps: (a) Record the probability level reported in each study associated with the relevant hypothesis; (b) turn to the Z score (standard normal deviate) table appearing in any elementary statistics text and find the Z score associated with each probability level; (c) sum these Z scores and divide this sum by the square root of the number of studies involved; and (d) refer this Z score back to the table and record the appropriate probability level. This probability describes the likelihood that the included studies' results were generated by chance. The user should be alert to the fact that a direction for the hypothesis should be chosen before the procedure is begun (Mosteller & Bush, 1954, p. 330). This means that a reported two-tailed p value supporting the hypothesis under consideration should be halved before the associated Z score is retrieved. A disconfirming p value should be halved and its associated Z score *subtracted* from the sum of the supporting studies.

The Stouffer method has many advantages, not the least of which is ease of employment. As Mosteller and Bush (1954) point out, however, even more precision can be built into this procedure if the reviewer weights (or differentially assigns importance to) studies within the body of literature. The Stouffer method allows the reviewer to weight each standard normal deviate by the size of the sample on which it is based or by other desirable characteristics such as internal or external validity. Thus, a reviewer can make adjustments based on methodological rigor before the statistic is generated. Studies that are viewed as "sound" can be weighted more heavily than "unsound" studies, if the reviewer so desires.

The formula for the weighted Stouffer method, when sample size is the weighting factor, is:

$$Z_{ma} = \frac{N_{s1}Z_{s1} + N_{s2}Z_{s2} + \cdots N_{sn}Z_{sn}}{\sqrt{N_{s1}^2 + N_{s2}^2 + \cdots N_{sn}^2}}, \qquad (2)$$

where $N_{s1} \cdots N_{sn}$ = the number of subjects in each included study, and all other quantities are defined as before. In this case, the modification requires that each study's Z score be multiplied by the number of subjects in the study before the scores are summed. This numerator is then divided by the square root of the squared and summed individual study sizes. The formula given here is weighted by sample sizes rather than another criterion because sample size is the most objective weighting criterion. Other less objective criteria have been convincingly employed, however (e.g., Stickell, 1963). The sample-size weighting means that larger studies are given greater importance. In comparison to the unweighted method, the weighted method will lead to a lower probability level when larger studies produce larger Z scores and a higher probability when smaller studies produce larger Z scores.

Studies needed to reverse a conclusion. We can state with some confidence that no literature review will uncover every relevant hypothesis test ever conducted (Rosenthal, in press, has referred to this as the "file drawer problem"). The Stouffer method has the advantage of allowing us to easily compute what could be called a fail-safe number. With the unweighted procedure we can ask the question "How many studies totaling a null hypothesis confirmation would be needed to reverse the conclusion that a relationship exists?" To state this numerically, we ask, "How many studies showing a *summed* Z score total of zero would be necessary to raise the overall probability level to about .05, or perhaps .10?" For the $p < .05$ level, the fail-safe formula would be:

$$N_{fs.05} = \left(\frac{Z_{s1} + Z_{s2} + \cdots Z_{sn}}{1.645}\right)^2 - (N_s), \qquad (3)$$

where $N_{fs.05}$ = the number of additional studies needed to increase the meta-analysis probability to above .05, and all other quan-

tities are defined as before. This formula is a direct algebraic manipulation of the unweighted formula. It requires that (a) the sum of the Z scores for known studies be divided by 1.645 (the Z score associated with $p < .05$, two-tailed); (b) this quantity be squared; and (c) the number of known studies be subtracted from it. The resulting quantity is the number of *additional* studies showing a summed null relationship needed to increase the meta-analysis probability above the .05 level of significance. Other significance levels can be used by replacing the denominator on the right with the critical Z value. Obviously, the fail-safe N should be presented only when a significant overall probability level can be reported.

The fail-safe N is an important descriptive statistic in that it allows a reader to easily evaluate the "strength" exhibited in a review against the felt completeness of the reviewer's sampling procedure. However, a limitation of the fail-safe N should also be pointed out. It is an appropriate guide for the reader *only* if the assumption of a summed null relation in undiscovered studies is acceptable. It is always possible that a smaller number of studies exist that have a summed Z score of equal but *negative* value to the sum of those reviewed. The plausibility of this alternative also should be considered by a reader. The illustration below includes both a weighted and unweighted Stouffer procedure and a fail-safe N. All three procedures are recommended for future reviews.

Describing relationship strength. Observers of psychological research have long bemoaned the infrequent reporting of measures of relationship strength, or effect sizes, in the literature (e.g. Bakan, 1966; Levy, 1967). As O'Brien and Shapiro (1968) point out, the usual criteria for gauging the importance of a study, its level of significance, are numbers bound tightly to the size of the sample involved. Significance testing, then, which compares an observed relation to the chance of no relation, becomes less informative as evidence supporting a phenomenon accumulates. The question turns from "whether" to "how much." Effect-size measures that are free of sample-size influence, therefore, ought to be an integral part of all literature reviews, especially when the reviewer concludes that, in fact, a relation exists.

There is an effect-size measure appropriate for every kind of research design or analysis. Jacob Cohen (1977) presents a definitive catalogue of these measures. It is the present author's hope that Cohen's work will continuously grow in importance. Here Cohen's d index is illustrated:

$$d = \frac{M_a - M_b}{SD}, \tag{4}$$

where M_a and M_b = the means of the two groups compared, and SD = the pooled estimate of the population standard deviations. The d index is chosen because it is simple, it is "scale free" (i.e., the standard deviation adjustment indicates that studies using different measurement scales can be compared), and it is applicable to a plurality of the studies in social psychology. It requires that only two means be compared, but even in most factorial designs we find that each independent variable is represented by two conditions. If more complex hypotheses are under consideration, alternate effect-size indexes are readily available in Cohen's book.

The d index is a number that tells how far apart the means of our two groups are in terms of their common standard deviations. For instance, if $d = .2$, it means that two tenths of a standard deviation separate the two sample means. In Cohen's terminology, a d index equaling .2 corresponds to a "small" effect size, with .5 being "moderate," and .8 being "large." This classification may leave something to be desired in terms of intuitive appeal. For this reason, Cohen (1977) also presents "percentage of distribution overlap" measures like the one in use by Smith and Glass (1977), cited earlier. The overlap measure illustrated here, called U_3, tells what percentage of the population with the smaller mean is exceeded by 50% of the population with the larger mean. Put more conversationally, "how much of the smaller-meaned group is exceeded by the average person in the larger-meaned group?" A table for converting the d index to U_3 is presented by Cohen (1977, p. 22). As an example, assume Groups

A and B have been compared and a d index of .2 is found, with Group A exhibiting the larger mean. The U_3 measure tells us that the average person in Group A has a score greater than 58% of the people in Group B.

The reader may wonder how this effect-size analysis can be carried out when means and/or standard deviations are not reported in an experimental write-up. Friedman (1968) has shown that when these quantities are not reported, the d index can be estimated from the formula:

$$d = \frac{2t}{\sqrt{df}}, \qquad (5)$$

where t = the reported t value (of $\sqrt{F}$ if analysis of variance is used), and df = the associated degrees of freedom for error. Instances will exist where neither means, standard deviations, nor t values will be reported. This problem is addressed in conjunction with the illustration presented below.

To summarize, a meta-analysis "package" has been suggested that includes the following statistics: (a) a Stouffer Z score; (b) a weighted Stouffer Z score; (c) a fail-safe N; (d) a d index of relationship strength; and (e) a percentage of overlap of distributions measure, U_3. The remaining tasks, then, are to illustrate the application of these procedures and to address the problems one encounters in doing so.

An Illustration: Do Females Conform More Than Males?

An area in social psychology where enough data have been accumulated to warrant meta-analysis is that of sex differences in conformity. Maccoby and Jacklin (1974) uncovered 47 independent tests of this relationship. Sex and conformity is chosen here because (a) the independent variable realization need not be explained; (b) the research designs and dependent measures are familiar to most social psychologists, so limited space is needed for their description; and most importantly, (c) Maccoby and Jacklin's literary combination of studies provides an excellent counterpart to the statistical combination. By choosing an area in which a traditional review already exists and by employing only the earlier cited studies in the meta-analysis, it is possible to compare the conclusions and precision of the two techniques. Essentially, Maccoby and Jacklin's conclusions are supported, though differences in some inferences are also apparent.

As hypotheses for the present study, then, Maccoby and Jacklin's (1974) *interpretation* of the sex differences in conformity literature will be used. The following passages, I believe, best summarize their inferences from the body of evidence:

> 1. All that can be said at this point is that the results are inconsistent, and that when Asch experiments are considered in conjunction with other conformity studies, neither sex shows an overall tendency to be more susceptible to social influence from peers. (p. 271)
>
> 2. In face-to-face encounters, when an individual must openly disagree with the opinion of others, as is the case in the Asch situation, women somewhat more often conform to others' judgments, but inconsistency of the findings and the frequency of sex similarity are striking. (p. 268)
>
> 3. Studies on the effects of persuasive communications have a more consistent outcome . . . On these grounds no overall difference in susceptibility to social influence would be expected. In any case . . . none is found. (p. 268)

Hypothesis confirmation in this meta-analysis means not only that the predicted relations are supported but also that Maccoby and Jacklin's earlier inferences have been upheld.

The studies sampled. The literature serving as data was Maccoby and Jacklin's 47 cited studies. No attempt was made to supplement or update the earlier review. This was done so that the statistical combination was yoked to the literary combination according to evidential base.

The data included 35 studies appearing in the *Journal of Personality and Social Psychology*, 5 in *Developmental Psychology*, 4 in *Child Development*, 2 in the *Journal of Social Psychology*, and one in the *Journal of Experimental Child Psychology*. The mean year of publication is 1969, with the earliest year of appearance 1958, and the latest, 1974. Twenty-one of the studies were published between 1968 and 1970. Twenty-four studies

used college-age samples, with the rest choosing younger subjects.

The most striking characteristic of the sample is that only published studies are included. Maccoby and Jacklin (1974) note that "some information is lost owing to the selection that occurs in the publication process itself" (p. 3). Most distressing is that, as Maccoby and Jacklin point out, "negative findings probably constitute the most frequent omissions from the literature" (p. 5). Essentially, two kinds of bias are operating here. First, we are less likely to see null results in published form. Second, we are less likely to see results that contradict previously published findings. This selection bias operates both on the decision of researchers to submit reports and on journal reviewers. The bias in the sampling process highlights the importance of calculating the fail-safe *N* before making inferences. Readers of a review should ask themselves, "How many studies are missing, given the sampling procedure employed?" A fail-safe *N* surpassing this estimate should increase the readers' confidence in the conclusions.

Sampling procedures more exhaustive than Maccoby and Jacklin's choice are available. Convention programs, computer-assisted searches, and *Dissertation Abstracts International* are all alternate or supplemental sources to professional journals. Rosenthal (1976) applies the interesting technique of separately analyzing dissertation research, under the assumption that this sample contains the least "confirmatory" bias (mitigating the "confirmatory" bias in published papers, by the way, is the argument that published research is conducted by the more capable researchers).

The analysis design. To test the first hypothesis (that no overall difference in conformity associated with gender appears in the literature), the studies were analyzed as a single group. To test the second and third hypotheses (relating to situation distinctions), the studies were divided into three categories. The first category contained Asch-type (Asch, 1956) experiments, in which subjects had face-to-face interaction with either other subjects or an experimental confederate. The second category included studies where conformity to a fictitious group norm or to a simulated other was measured. The final category was composed of persuasive communication or social reinforcement (Insko, 1965; Insko & Cialdini, 1969) experiments. The Asch-type studies used primarily agreement with a group of peers' erroneous perceptual judgment as the dependent variable. Fictitious group norm studies used primarily opinion change, and persuasive communication studies used mainly attitude change to measure conformity. It is not clear whether Maccoby and Jacklin's (1974) distinction concerning face-to-face interaction intended the categorization employed here. Their remark may refer to both in-person and simulated-other experiments. In either case, the results support the face-to-face distinction.

This three-way classification led to the exclusion of three studies because they were correlational (Baumrind & Black, 1967; Samorjzyk, 1969; Whiting, 1963) and two studies because they related to behavior in experimental situations (Cook et al., 1970; Dillehay & Jernigan, 1970). In addition, three studies were excluded because they were conducted on non-American subject populations (Beloff, 1958; Bronfenbrenner, 1970; Frager, 1970). Of the excluded studies, Bronfenbrenner reported that Russian males were more conforming than Russian females, and Cook et al. reported that females were more compliant to experimental deception. No other excluded study reported significant sex differences. Finally, the study by Sistrunk and McDavid (1971) was not included because of its special place in the literature, to be noted later. The exclusions encompassed 19% of the sample but permitted the following generalizations to be made about the studies remaining in the analysis: (a) They all involved peer influence; (b) they all were performed using white Americans (or results reported here are relevant to this population); (c) they all included an experimenter-controlled introduction of the conformity-producing stimulus.

After the 9 studies not fitting into a category were dropped, 38 studies remained. Sixteen studies fell into the Asch-type category, 8 into the group norm category, and 14

into the persuasive communication category. Tables 1 through 3 present this categorization. The mean year of journal appearance for each grouping is nearly identical. This indicates that there was no research paradigm shift in sex and conformity studies over the covered period. Also, the tables show that the average Asch-type experiment was conducted using about 17 more subjects than the average group norm experiment (Asch-type = 141.1; group norm = 124; persuasive communication = 132.7). All three experiment-size means, however, are well within a standard deviation of each other (Asch-type SD = 87.6; group norm SD = 72.8, persuasive communication SD = 88.5). This analysis of category differences helps rule out alternative hypotheses, should different results be found for different categories.

Obtaining data about experiments. A number of problems arise when the reviewer attempts to extract from each experimental report the statistics needed for combination (here, *t* values and *p* levels). The most glaring problem is that many studies finding no differences do not report the statistics upon which this inference is based. In the present analysis, 12 of the 38 categorized studies (32%) reported no statistics. Creating even more frustration was the finding that 4 studies (11%) reported *t* (or *F*) values without mentioning the direction of the effect! In each case, a simple finding of "no difference" is reported. Although the premium on space in professional journals is appreciated, much of this "planned obsolescence" that researchers build into their reports can be avoided. Instances were found in which analysis of variance summary tables were presented with nonsignificant *F* values replaced by lines. This does not save space. The statement that "no differences were found between Groups A and B" can be replaced with the statement that "a nonsignificant difference was found, with Group A higher than Group B." At the least, directional statements along with their statistical basis ought to appear for all main effects tested. The increase in length that this may entail will be amply repaid through the increased amount of time the report will contribute to the area of interest. It should also be noted that the present

[a] Sistrunk reports more conformity among black females than males but no differences among whites.

42%-incomplete reporting rate is probably higher than the rate that will be found in other areas. This is because the experiments included here typically studied sex differences only secondarily. Most researchers will take more care in reporting primary findings.

The best strategy for dealing with incomplete data reports is to assume an exact finding of no difference. Thus, such studies are treated below as having uncovered a *t* value of 0 with a probability of .50. As meta-analysis combined probabilities become lower, we can assume that this procedure increases "conservative" bias in our estimations and inferences.

A second difficulty encountered when statistics are being collected is that some studies employ multiple dependent measures. In such an event, alternate courses of action are open to the reviewer. First, all dependent variables can be included. This procedure means that some experiments will contribute to the overall probability more than others. If the reviewer does not wish this to be so, each dependent variable within a study can be weighted so that the sum of each study's measures is equal. A third strategy is to choose the major dependent variable (i.e., the one closest to the sample description) and exclude all others. This is the strategy used here.

Other problems related to multiple measures arise when (a) separate papers report different dependent measures collected on the same subjects or when (b) the same researcher (laboratory) reports several studies. These problems (as well as the sampling bias referred to above) diminish the *independence* of data involved in meta-analysis. At present, the more elegant statistical adjustments for nonindependence of observations (most notably, adjustments in degrees of freedom) can only be subjectively approximated in meta-analytics. This can be accomplished through the reviewers' weighting decisions. Thus, if Researcher X has produced four similar studies in a 2-year period, a cautious meta-analyst might individually weight these studies less heavily than a similar single study produced from a different laboratory.

Another problem in data collection arises when both parametric and nonparametric statistics appear in the literature. Only one instance of nonparametric use was encountered in this analysis (Hollander, Julian, & Haaland, 1965). The procedure used was to extrapolate all important values from the reported probability level. A more equal mix of statistics based on differing assumptions might lead to the use of other procedures (i.e., combining raw data from expected-frequency-type studies and treating these separately).

A final problem in data retrieval relates to levels of significance. Care should be taken to recompute the relevant significance levels presented in the individual reports. Probabilities falling between .05 and .01 are often

reported as $p < .05$. For testing the null hypothesis, this procedure is legitimate, but more accurate Z scores will be retrieved if more accurate probabilities are computed. With the introduction of high-speed computers, the rounding of p levels is practiced less often. However, the reviewer cannot easily discern whether this has been done.

The reader may have noted that the procedures outlined above (gathering t values, examining means, recomputing probabilities) represent a significant departure from traditional literary reviews regardless of whether studies are statistically combined. It would be interesting, then, to gauge separately the increased precision created by means of data retrieval and by the combining procedures. For this reason, the Stouffer methods have been performed on both the p levels gathered by the procedures outlined above and the p levels presented in Maccoby and Jacklin's (1974) annotated bibliography. These latter probabilities take one of four values: .50, .05, .01, and .001.

Results. In brief, the hypotheses can be stated as follows:

1. When the body of evidence is examined as a whole, neither sex will show an overall tendency to be more susceptible to social influence from peers.

2. In face-to-face encounters, women more often than men will conform to others' judgments. However, (a) there will be inconsistency of the findings, and (b) the frequency of sex similarity will be striking.

3. Studies on the influence of persuasive communications will show no overall difference in susceptibility to social influence.

Testing Hypothesis 1 first entailed combining Z scores over 46 studies (with Sistrunk & McDavid, 1971, excluded). Table 4 presents most resulting statistics (all p levels are reported as one-tailed). When the probabilities reported in Maccoby and Jacklin (1974) served as data, the unweighted Stouffer method led to a Z_{ma} of 2.13 with a one-tailed probability of less than .015. The weighted method produced a Z_{ma} of 1.18 with $p < .12$.

The Stouffer procedures were then repeated with only the Z scores of the 38 categorized studies included. Using the Maccoby and Jacklin probabilities led to an unweighted Z_{ma} of 2.35. Such a score would occur less than 1% of the time given that females actually do not conform more than males. When the Z scores retrieved from the primary

Fail-safe *N*	40	129	84	125	—	—	—	—

Note. All *Z* scores are based on 38 studies; *p*s are one-tailed.
[a] Asch (1956).

sources were used, the unweighted Z_{ma} rose to 3.44, an event that chance produces less than 5 in 10,000 times. If Maccoby and Jacklin's data are used, the fail-safe *N*, the number of null-totaling studies needed to raise the observed probability to above 5 chances in 100, is 40. Based on the retrieved data, a fail-safe *N* of 129 is found.

It seems, then, that taken as a whole, the body of evidence supports the conclusion that females conform more than males. If we restrict our inference to American subjects in experimenter-controlled, peer-influence situations, we can make this statement more confidently. This conclusion is at odds with Maccoby and Jacklin's, which saw "no overall tendency" for females to be more conforming. In this instance, the literary and statistical combinations led to differing interpretations of the data. In addition, the retrieving of data from primary sources led to a more confident conclusion of sex differences than did the annotated bibliography. The *p* levels produced by the two gathering methods differ by 89 uncovered studies needed to reverse the conclusion.

Tests of Hypotheses 2 and 3 show less dramatic differences between the approaches. Hypothesis 2 entailed analyzing separately the Asch-type and group norm experiments. The unweighted Z_{ma} for only Asch-type experiments was 4.11 with Maccoby and Jacklin's *p* levels and 4.87 with retrieved *p* levels. Both occur by chance less than 1 in 10,000 times. The weighted Z_{ma} scores are again lower, being 3.56 and 4.03, respectively, but are still highly significant ($p < .0005$ and $p < .00005$, respectively). The fail-safe *N* at $p = .05$ for Maccoby and Jacklin's data was 84, whereas the fail-safe *N* for retrieved data exceeded this by 41.

Analysis of group norm experiments produced the first set of nonsignificant results. As Tables 2 and 4 show, there was a slight tendency for group norm studies to report more conforming in males than females (as the negative Z_{ma} score indicates). This tendency was far from significant, however.

Hypothesis 2, then, was clearly supported. As Maccoby and Jacklin (1974) conclude, females do seem to conform more than males in face-to-face situations. The difference in conclusion strength introduced by reporting precision also seems negligible. What does go unsupported is Maccoby and Jacklin's conclusion that the results show inconsistency. In face-to-face encounters, only 2 of 16 studies report "small" effects contradicting the overall conclusion. The appearance of these anomalies could have been generated by undiscovered interactions or by chance. To label the overall results as "inconsistent" because of them is to attach undue importance to their probabilistic nature.

Also unsupported is Maccoby and Jacklin's conclusion that "the frequency of sex similarity" is striking. A more legitimate statement would be that the size of the sex difference may be smaller than the reviewers anticipated or the cultural stereotype predicted.

The effect-size analysis allows these impressions to be quantified. As Table 1 indicates, the average d index for Asch-type experiments was .28. This shows that on the average, the male and female distribution midpoints were .28 standard deviations apart (assuming that normality holds). In terms of overlap (U_3), it is found that the average female conformed more than 60% of the male population (of course, the sample and setting restriction also restrict the generalizability of this statement). Further, since the d index exhibits a standard deviation of .37, we can expect that future experiments will exhibit d indexes between .08 and .48 about 95% of the time. Alternatively, Asch-type studies should show the average female conforming more than between 54% and 69% of the male sample, 95% of the time.

Hypothesis 3 is supported by the data presented in Tables 3 and 4. The Maccoby and Jacklin (1974) data produced a Z_{ma} of 0, whereas the weighted procedure with retrieved data produced the largest, though still nonsignificant, Z_{ma} of 1.10 ($p < .14$). Neither reporting precision nor method seems to influence this conclusion.

To summarize, then, the statistical combination of studies led to a conclusion different from the literary one when it showed an overall tendency for females to conform more than males. Increased precision in data gathering also weighed against the null hypothesis. When the studies were categorized, Maccoby and Jacklin's conclusion that sex differences would arise only in face-to-face interactions was upheld. However, the interpretation of this effect as inconsistent and exhibiting striking similarity between the sexes was questioned. Finally, it should be noted that, as one would expect, the two methods differ most in the "least clear" instance. Although in this instance the ability to categorize studies meant that the differing overall conclusions were substantively inconsequential, this may not always be the case.

The Eagly (1978) Update

Since the completion of the above meta-analysis, another review of sex differences in conformity research has appeared (Eagly, 1978). This literary review, based on considerably more studies than Maccoby and Jacklin's, also proves instructive when compared to meta-analytics.

Eagly provides a three-way classification of conformity studies nearly identical to the one employed above. With regard to Asch-type (group pressure) studies, the available evidence is summarized as follows: Of the 61 studies, 38 (62%) reported no difference, 21 (34%) found females to be significantly more conforming, and 2 (3%) found males significantly more conforming (Eagly, 1978, p. 92).

Eagly's criterion for significance is a main effect reaching the .05 chance level for null acceptance. A meta-analytic chi-square produced by Eagly's data has a value of 55.94.[1] Such a statistic is almost impossible to produce by chance (a chi-square value of 10.83 appears by chance once in 1,000 observations). To reduce the observed frequency of sex differences to the exact chance expectation, 361 studies *each* showing a null relation would have to exist but be undiscovered. About 221 undiscovered null studies would be needed to raise the expected number of confirmations close enough to the presently observed number so that chance could not be ruled out at the .05 level.

For fictitious group norm studies (not involving group pressure) Eagly reports 22 studies, with 2 reporting more conformity in women and 1 reporting more conformity in men. Eagly's conclusion that no difference is found here is justified through meta-analysis. Only 19 undiscovered null studies would reduce the present observations to an exact chance rate. For attitude change (persuasion) studies, 51 studies showing no difference, 10 showing greater female persuasibility, and 1

[1] In generating this statistic, I have used the expected values of 5 for significant differences (Rosenthal, 1978, suggests that no expectation less than 5 be used) and 54 for null differences. These numbers correspond to a .08 level of significance, implying that the reported chi-square value is conservative. I ignored the below-expectation (3%) occurrence of greater male conformity. A similar procedure is used throughout this discussion.

showing greater male persuasibility are reported. Eagly (1978) interprets these studies as indicating a very slight balance favoring female influenceability (p. 95). The associated meta-analytic chi-square statistic is 5.45, which is significant between the .02 and .01 levels. Undiscovered null studies numbering 139 would reduce the observed frequencies to a chance rate. About 59 null studies would reduce the observed patterns' relation to chance to above the .05 level.

In sum, Eagly (1978) states that "the modal finding in the conformity literature is no difference between the sexes" (p. 93) and that "in group pressure settings, a substantial minority of studies has reported differences in the female direction" (p. 93). These statements are correct but may be misinterpreted. They ought to be accompanied by a statement emphasizing that except in the case of extremely strong effects and/or large-sized experiments, we would *expect* the modal result to be a null confirmation. Further, it is evident that in the case of sex differences in group pressure conformity, the available "substantial minority" of null rejections is so substantial as to be almost impossible to create by chance.

Discussion

With the illustration in hand, it seems appropriate to conclude by addressing some of the more practical advantages of statistical combinations, in contrast to the abstract arguments presented earlier. Some limitations should also be pointed out.

First, the issue of inconsistency in experimental results deserves fuller examination. Other authors make statements whose eloquence cannot be improved upon here. As Saveggia (1974) offers:

> methodological principle overlooked by writers of research . . . reviews is that research results are *probabilistic*. What this principle suggests is that, in and of themselves, the findings of any single research are meaningless—they may have occurred simply by chance. It also follows that, if a large enough number of researches has been done on a particular topic, chance alone dictates that studies will exist that report inconsistent and contradictory findings! Thus, what appears to be contradictory may simply be the positive and negative details of a distribution of findings. (p. 397)

The disadvantages of maintaining our present use of the word *inconsistent* are listed by Light and Smith (1971):

> First, a great deal of information, much of which might be potentially valuable, would be thrown away. Second, a decision would be postponed for at least the length of time required by the new research. Third, from the point of view of the next reviewer of the literature, this new research would simply be the fourteenth in a set of studies. No matter what the result, for the next reviewer the contradictions remain. Thus, for any research, it is worth making an attempt to find a way to combine and reconcile conflicting studies. (p. 430)

The adoption of statistical procedures, then, will lead to less frequent conclusions of inconsistency. The use of the word *inconsistent* should occur only when experiments reveal strong relations in *opposite* directions.

When this stricter definition of inconsistency *is* applicable to a research area, a second advantage of meta-analysis will become evident. Often, inconsistency is an indication that undiscovered interaction between variables exists. Statistical combinations allow for the testing of certain kinds of interaction without running additional subjects. Experimental differences in time, location, operational definitions, age of subject, and so on can be used to cluster research (Feldman, 1971). Statistical procedures can then test the importance of cluster distinctions.

Clustering experiments will also lead to fuller awareness of sample restrictions relevant to the results in hand. In the present example, categorizing research led to uncovering what is a fairly typical generalization restriction in social psychological research (i.e., the results apply to white Americans, 21 years old or younger, in peer influence situations). These restrictions become possible mediators for future research to investigate. They are, however, a function of the available evidence and not of the combining method.

It should be emphasized that the ability to test certain interactions with meta-analysis does not mean that all problems of conceptualization and methodological artifact can be resolved in this manner. Whether con-

formities in Asch-type and in persuasive communication experiments are truly phenomena of a similar nature is not addressed by meta-analysis. Further, as in evaluating a single study, alternative conceptualization of included independent variables may rival the one offered. Thus, Festinger and Carlsmith's (1959) F statistic cannot tell us whether dissonance or self-perception is behind the "more attitude change for less reward" finding. The Z_{ma} statistic in a present day meta-analysis on replications of this study would not address this issue either. Finally, studies sharing a certain methodological technique become open to rival hypotheses (we hope, of course, that undiscovered method weaknesses are distributed throughout the research process and are equally likely to weigh against as for a given hypothesis). The study by Sistrunk and McDavid (1971) provides an example of restricting an inference by varying a method. They noted that one characteristic of Asch-type studies was a consistent use of perceptual dependent variables. Their results showed that face-to-face conformity differences may be restricted to this certain type of judgment only.

A final advantage of meta-analysis deals with the power of research to uncover relationships. As earlier stated, the probability of a study's finding significance is tied to the number of subjects involved. An example of this is present in Table 1. The experiments by Costanzo and Shaw (1966) and by Gerard, Wilhelmy, and Conolley (1968) uncovered effects of almost equal magnitude. Yet, because Gerard et al. ran 58 more subjects, their effect size proved significant. Meta-analyses should, as a matter of course, contain effect-size estimates, and these should be used to guide future research.

To conclude, this article has attempted to introduce and provide argument for the adoption of more rigorous procedures for drawing inferences from bodies of evidence in social psychology. An example was presented employing as hypotheses a literary interpretation of an area of research and using the exact same studies as data. This procedure made it possible to compare the two methods with conceptual issues controlled. Some statistical conclusions differed in direction and con dence from the literary ones.

Pleas for the increased use of archival da are often heard. Add one more voice, stati that the best archival data we have are o *own* records.

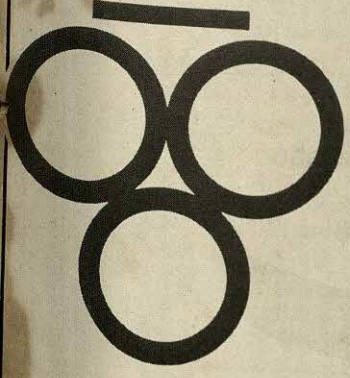
APA EMPLOYMENT BULLETIN

Possibly your key to greater career opportunities.

Each month 125 to 150 position openings are listed by geographical area and employment field for psychologists with a minimum of a Master's degree. Members may also publish availability notices. Coded identification numbers assure confidentiality. Ideal for employers, students, and Master's and Ph.D graduates.

A one year subscription is as little as $9.00 for members, $16.00 for non-members. If you're in a hurry, First Class delivery is available for an additional $4.00.



For more information, contact:
The Editor, Employment Bulletin,
or send your order to:
American Psychological Association
Subscription Dept.-Employment Bulletin
1200 Seventeenth St., N.W.
Washington, D.C. 20036

Methodology in Clinical Research

Special issue of the **Journal of Consulting and Clinical Psychology** *August 1978*

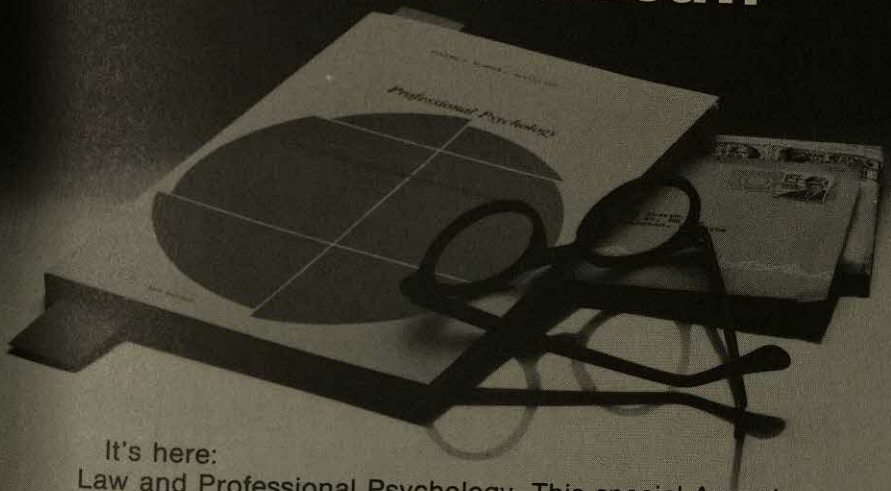
Major methodological aspects of clinical topic areas are described and discussed. Topic areas include smoking and addiction, marital and child treatment, sex roles, obesity, and others.

Contributors include, the editor, Brendan A. Maher, Alan E. Kazdin, Richard M. McFall, Peter E. Nathan, David Lansky, and Judith Worell to name a few.

Copies of the special issue are available at $6 each, prepaid. Discounts on bulk orders are also available. To order single copies or for more information on bulk orders write:

Subscription Department
American Psychological Association
1200 17th Street, N.W.
Washington, D.C. 20036

NOW: INFORMATION ABOUT THE LAW AND PSYCHOLOGY.



It's here:
Law and Professional Psychology. This special August 1978 issue of **Professional Psychology** brings you thirteen original articles full of fresh thought and constructive recommendations on the issues that vitally affect your day-to-day practice. You'll find precautions you may take to protect yourself as a professional and a plan for improving investigations of malpractice claims. Expert witness testimony, jury selection, civil commitment, confidentiality and privilege, minor's consent to treatment, and the use of psychological devices are critically examined.

Send your order today. And soon you'll receive this special issue.

Single copies of the issue are available for $5 each. All orders $25 or less must be prepaid. Make and send checks payable to:

American Psychological Association
Order Department
1200 17th Street, N.W.
Washington, D.C. 20036

Student-involving introductory texts

NEW

EXPERIENCING SOCIAL PSYCHOLOGY: Readings and Projects

Ayala Pines and **Christina Maslach,** both of the University of California, Berkeley

This integrated reader/project manual features research articles and popular readings on current topics, classical problems, and new content areas such as social pathology, ethical dilemmas of researchers, and the problems of "burn-out" among helping professionals. The introduction shows students how to read such material critically, while thoroughly class-tested projects make this material concrete by involving students in a variety of independent activities, including data collection, theoretical critiques, and group exercises.

Random House/1979/320 pages paperbound/Order Codes: 31281, 32168 (I.M.)

PERSONALITY: An Introduction

John Lamberth, Herbert Rappaport, and **Margaret Rappaport,** all of Temple University

Each chapter of this comprehensive text was written by the author with the greatest expertise and interest in the area, making the whole text completely authoritative. Every major aspect of personality study — assessment techniques, development, research, and applications — is fully covered and viewed in the light of all theoretical approaches, giving you the most comprehensive, balanced, up-to-date presentation possible.

The Journal of Personality and Social Psychology publishes original reports of research, methodology, theory, criticism, and literature review in the fields of personality and social psychology of normal processes and populations. Submitted manuscripts should delineate an important question and provide a clear answer to it. In the case of research reports, this will often require demonstration that the reported results are generalizable beyond a single research setting. Consult the editorial in the January 1976 issue (Vol. 33, pp. 1–7) for a detailed statement of policies and instructions to authors.

Manuscripts: Submit manuscripts in quadruplicate, prepared according to the *Publication Manual of the American Psychological Association* (2nd ed.). Copies should be highly legible and will not be returned to authors unless they are original typewritten copies. Mail manuscripts to the Acting Editor, Clyde Hendrick, Department of Psychology, Box 8185, University of Miami, Coral Gables, FL 33124 until March 31, 1979. After April 1 mail manuscripts according to instructions on page 314.

Required supplementary information: Manuscripts cannot be reviewed for publication unless the author provides supplementary information in the following categories: (a) a cover letter that indicates the relation (or the lack of relation) of the submitted manuscript to other papers by the same author(s) that are currently submitted, in press, or recently published; (b) one copy of each such related paper; (c) one copy of a statement of the procedures of the research reported in the submitted manuscript in sufficient detail to serve as a guide for conduct of an exact replication; and (d) one copy of the summary tables (e.g., correlation tables, analysis of variance summaries) for the *major* analyses reported. If it appears that the supplementary materials in categories (c) or (d) might be bulky, the author should exercise judgment and restraint in selecting what to send. It is not necessary to send supplementary material that repeats verbatim manuscript content.

After a manuscript is accepted, authors will be expected to provide assurance that their data are available in unanalyzed form for reanalyses by other investigators and that their research procedures were consistent with the American Psychological Association's published principles of research ethics, except insofar as may be detailed otherwise in the manuscript.

Copyright and Permission: All rights reserved. Written permission must be obtained from the American Psychological Association for copying or reprinting text of more than 500 words, tables, or figures. Permission is normally granted contingent upon like permission of the author, inclusion of the APA copyright notice on the first page of reproduced material, and payment of a fee of $10 per page, table, or figure. Abstracting is permitted with credit to the source. Permissions and fees are waived for authors who wish to reproduce their own material for personal use; fees only are waived for authors who wish to use their own material commercially. Permission and fees are waived for the photocopying of isolated articles for nonprofit classroom or library reserve use by instructors and educational institutions. Libraries are permitted to photocopy beyond the limits of U.S. copyright law: (1) those post-1977 articles with a code at the bottom of the first page, provided the per-copy fee indicated in the code is paid through the Copyright Clearance Center, P.O. Box 765, Schenectady, NY 12301; (2) pre-1978 articles, provided that the per-copy fee stated in the Publishers' Fee List is paid through the Copyright Clearance Center, P.O. Box 765, Schenectady, NY 12301. Address requests for reprint permission to the Permissions Office, APA, 1200 Seventeenth Street, N.W., Washington, D.C. 20036.

Subscriptions: Subscriptions are available on a calendar year basis only (January through December). Nonmember rates for 1979: $60 domestic, $64 foreign, $6 single issue. APA member rate: $20. Write to Subscription Section, APA.

Change of Address: Send change of address notice and a recent mailing label to the attention of the Subscription Section, APA, 30 days prior to the actual change of address. APA will not replace undelivered copies resulting from address changes; journals will be forwarded only if subscribers notify the local post office in writing that they will guarantee second-class forwarding postage.

Reprints: Authors may order reprints of their articles from the printer when they receive proofs.

Back Issues and Back Volumes: For information regarding back issues or back volumes write to Order Department, APA.

Microform Editions: For information regarding microform editions write to any of the following: Johnson Associates, Inc., P.O. Box 1017, Greenwich, Connecticut 06830; University Microfilms, Ann Arbor, Michigan 48106; or Princeton Microfilms, Princeton, New Jersey 08540.

Published monthly in one volume per year by the American Psychological Association, Inc., 1200 Seventeenth Street, N.W., Washington, D.C. 20036. Printed in the U.S.A. Second-class postage paid at Washington, D.C., and at additional mailing offices.

Self-Deception: A Concept in Search of a Phenomenon

Ruben C. Gur
University of Pennsylvania

Harold A. Sackeim
Columbia University

The concept of self-deception has received little empirical investigation despite its broad implications for theories of personality and consciousness. Four criteria, based on a logico-linguistic analysis, are presented as necessary and sufficient for ascribing self-deception: To be self-deceived an individual must hold two contradictory beliefs; these beliefs are held simultaneously; one belief is not subject to awareness; and the nonawareness of this belief is motivated. Two experiments are described that examine whether misidentifications of the voices of oneself and others fulfill these criteria and are, therefore, instances of self-deception. In Experiment 1, it was found that when subjects were incorrect in their self-report identifications of voices, at some level of processing correct identifications had been made, and these subjects held contradictory beliefs. Obtrusive and unobtrusive measures indicated that for the most part, subjects were not aware of committing errors. Correlational data supported the contention that the errors were motivated. In Experiment 2, the hypothesized motivational contexts for the errors were manipulated by giving subjects pretreatments either of success or of failure. As predicted, the failure group committed more misidentifications of self, whereas the success group committed more misidentifications of others. Overall, the findings confirmed that some misidentifications of voices of self and others are instances of self-deception.

The concept of self-deception has received much attention in philosophical and literary writings (e.g., Camus, 1956; Fingarette, 1969; Gide, 1955; Sartre, 1958). Numerous psychologists have also discussed self-deception in accounting for a wide range of behavior. Meehl and Hathaway (1946) and Anastasi (1961) have argued that self-deception on the part of respondents contributes more to the lack of validity of self-report personality inventories than does other-deception, or conscious lying. In the area of motivation and personality, Hilgard (1949) claimed that self-deception constitutes a defining characteristic of all defense mechanisms. In the area of problem-solving behavior, Wason and Johnson-Laird (1972) in-

voked the concept of self-deception as a possible explanation of the persistence of subjects in maintaining hypotheses in the face of disconfirmation. Murphy (1970, 1975) related the concept of self-deception to possible interpretations of the experimental findings on perceptual defense. In fact, Mischel (1974) has viewed all neurotic behavior as instances of self-deceptive acts.

Despite the considerable role assigned to the concept of self-deception in several areas of study, there have been no attempts to demonstrate that any given set of behavior conforms to what is meant by self-deception. Philosophers have frequently remarked that determining what is meant by self-deception and demonstrating that people do deceive themselves have major implications for views concerning the structure of consciousness (cf. Fingarette, 1969; Sartre, 1958). For instance, findings that indicate that people do lie to themselves may also indicate that people can hold beliefs of which they are not aware and that the selective awareness of beliefs can be motivated. Within psychology it has been a long-standing tradition to assume that people are necessarily aware of their cognitions (Wundt, 1912/1973). Recently, however, studies have appeared that shed strong doubt on the validity of this view (Dixon, 1971; Erdelyi, 1974; Nisbett & Bellows, 1977; Nisbett & Wilson, 1977; Sackeim, Packer, & Gur, 1977). The claim that selective nonawareness of cognition can be motivated—the essence of what is entailed by the concept of self-deception—is particularly controversial.

Elsewhere, we have presented a logico-linguistic analysis of what is meant by the concept of self-deception (Sackeim & Gur, 1978). On the basis of this analysis, four criteria have been offered as necessary and sufficient for the ascription of self-deception. Here, we will present two experiments designed to test whether a phenomenon, misidentification of voices of self or others, fits these criteria. Such findings may be viewed as an experimental demonstration of the existence of self-deception.

Criteria Necessary and Sufficient for Ascribing Self-Deception

It has been noted that when it is assumed that people are necessarily aware of their cognition, the concept of self-deception is paradoxical (Canfield & Gustafson, 1962; Demos, 1960; Fingarette, 1969; Gardiner, 1970; Penelhum, 1966; Sartre, 1958; Siegler, 1962). This paradox has been formulated by Sartre (1958) as follows:

> The one to whom the lie is told and the one who lies are one and the same person, which means that I must know in my capacity as deceiver the truth which is hidden from me in my capacity as the one deceived. Better yet I must know the truth very exactly in order to conceal it more carefully—and this not at two different moments, which at a pinch would allow us to reestablish a semblance of duality—but in the unitary structure of a single project. How then can the lie subsist if the duality which conditions it is suppressed? (p. 49)

In the psychological literature, a similar paradox was raised by critics of research on subliminal perception and perceptual defense (Bruner & Postman, 1949; Eriksen & Browne, 1956; Howie, 1952). The point was made that in order for a perceiver to avoid perceiving a stimulus, the stimulus must first be perceived. When it is assumed that perception implies awareness of the percept, notions like subliminal perception and perceptual defense are paradoxical. Proponents of the existence of these phenomena (Dixon, 1971; Erdelyi, 1974) have argued that it is erroneous to assume that cognition must be subject to awareness. In support of this posi-

Jerre Levy, Jacob Nachmias, M. Frank Norman, Daniel N. Osherson, Michael Parrish, Richard Passingham, Paul Rozin, Martin E. P. Seligman, Richard L. Solomon, David Williams, Julius Wishner, and Donna M. Zucchi for their comments on an earlier version of the manuscript and Anthony G. Greenwald and several anonymous reviewers for their comments on the present version. We also thank Joseph Liran, who aided in setting up the instrumentation, and Jo Ann Chalal, Harvey Doppelt, Ron Kamnik, Lisa Litvin, Alan Luxenberg, Joseph Piperato, Shelley Steinberg, and Marjory Warner, who served as experimenters.

The order of authors is random.

Requests for reprints should be sent to Ruben C. Gur, Department of Psychology, University of Pennsylvania, 3815 Walnut Street, Philadelphia, Pennsylvania 19104.

tion, Nisbett and Wilson (1977) have summarized a sizable body of literature that indicates that people may lack awareness for both the contents and processes involved in cognition.

Rejection of the assumption that cognition is necessarily subject to awareness is implicit in the common use of the term *self-deception.* Often when people describe an individual as self-deceived, they state that "all along" or "deep inside" the individual holds a belief that contradicts an avowed belief. It is further implied in the common use of the term that the self-deceived individual, who holds such contradictory beliefs, does not do so gratuitously or out of ignorance; rather, one belief is not subject to awareness, in order to provide some psychological gain. Just as people attribute motivational determinants in cases of conscious lying, they view instances of self-deceit as implicating motivation. Accordingly, we have offered the following criteria as necessary and sufficient for ascribing self-deception to any given phenomenon:

1. The individual holds two contradictory beliefs (that p and not that p).
2. These two contradictory beliefs are held simultaneously.
3. The individual is not aware of holding one of the beliefs.
4. The act that determines which belief is and which belief is not subject to awareness is a motivated act.

Self-Deception: Reactions to Self-Confrontation

In the search for a phenomenon that fits the concept of self-deception, the self-confrontation experience provides a likely candidate. It has been shown that when subjects are confronted with audio- or videotape feedback of the self and others, feedback of the self is associated with considerable psychophysiological reactivity (Holzman, Rousey, & Snyder, 1966; Olivos, 1967; Sackeim & Gur, 1978), changes in affect and constriction in ideation (Duval & Wicklund, 1972; Holzman & Rousey, 1966; Holzman et al., 1966; Rousey & Holzman, 1967), and changes in self-concept (Alkire & Brunse, 1974; Boyd & Sisney, 1967; Duval & Wicklund, 1972; Gur & Sackeim, in press; Storms, 1973). Self-confrontation manipulations have also been shown to influence dream content (Castaldo & Holzman, 1967, 1969) and other behaviors that do not appear to be mediated by conscious awareness (Huntley, 1940; Wolff, 1943).

Differences in the direction and intensity of reactions to self-confrontation have been associated with experimental manipulations of self-esteem and with individual differences in personality (Davis & Brock, 1975; Duval & Wicklund, 1972; Gibbons & Wicklund, 1976; see Sackeim & Gur, 1978, for a review). These findings have led to the conclusion that individuals who hold negative attitudes about the self and score high on measures of cognitive discrepancy[1] find self-confrontation to be aversive and will tend to avoid it. On the other hand, people low in cognitive discrepancy do not find self-confrontation aversive and in fact will seek it out. Several studies have shown that people often fail to recognize their own voice, and sometimes people identify others as the self (Holzman et al., 1966; Huntley, 1940; Olivos, 1967; Wolff, 1943). The fact that there are individual differences in reactions to self-confrontation, and that some people find self-confrontation aversive while others seek it out, may indicate a motivational basis for the errors in identification.

The question we posed for investigation is whether individuals are engaging in self-deception when they avoid self-confrontation by misidentifying the self as others and when they artificially seek out self-confrontation

[1] Cognitive discrepancy is defined here as the extent to which individuals hold discrepant attitudes and beliefs about themselves. These discrepant cognitions may involve conflicts between what individuals believe themselves to be and what they believe they should be or wish to be. On paper-and-pencil personality inventories, items that a priori would tap this dimension are questions concerning dissatisfaction with the self. For example, on the Neuroticism scale of the Eysenck Personality Inventory (Eysenck & Eysenck, 1963), such an item would be "Do you often worry about things you should not have done or said?"

by misidentifying others as the self. Both of these errors involve distortions of reality. Mistaking self for others reflects an avoidance or a denial of an aversive event. Individuals who misidentify others as self commit a "narcissistic," self-projecting response. Our hypothesis, then, is that at least some misidentifications of self or others are instances of self-deception.

Experiment 1

Operationalizing the Criteria for Self-Deception

In order to demonstrate that misidentifications of self and others are instances of self-deception, it must be shown that when people commit such errors they fulfill the four criteria for ascribing self-deception. The operationalization of the criteria is presently outlined in specific relation to the procedure used in Experiment 1. Subjects were administered a simple identification task in which they were asked to indicate whether audio stimuli were tapes of their own or other people's voices. Galvanic skin responses (GSR) to each voice and reaction time of identifications were recorded. Subjects had completed a battery of personality inventories before the experimental session.

The First Criterion: Holding Two Contradictory Beliefs

The first criterion for ascribing self-deception requires evidence that when subjects misidentify a voice they hold contradictory beliefs. Subjects' self-report identifications of voices provide one index of beliefs. In affirming that a given voice is, for instance, that of another, a statement has been made concerning a particular belief. Levels of GSR reactivity to voices may provide another index of beliefs. In every relevant study that examined psychophysiological reactivity, it has been found that levels of arousal are substantially higher following self-confrontation as compared to confrontation with others (Holzman et al., 1966; Murray, 1963; Olivos, 1967; Sackeim & Gur, 1978; Verwoerdt, Nowlin, & Agnello, 1965; Dickinson & Ray, Note 1; Sackeim, Note 2). If subjects hold contradictory beliefs when they incorrectly identify voices, then their levels of GSR reactivity should be high when they misidentify voices of self as others (false negative responses) and low when they misidentify voices of others as self (false positive responses). This would indicate that when subjects committed such errors, at some level of processing correct identifications had also been made. This use of psychophysiological responding to determine whether subjects hold contradictory beliefs is similar in concept to the use of psychophysiological measurement in the detection of conscious lying (Lykken, 1959, 1974; Orne, Thackray, & Paskewitz, 1972) and to the employment of such measures in subception experiments (Dixon, 1971; Eriksen, 1956, 1958; Lazarus & McCleary, 1951).

The Second Criterion: Simultaneity of Beliefs

The second criterion for the ascription of self-deception requires that the two contradictory beliefs be held simultaneously. In the present experimental context this criterion is fulfilled by examining the psychophysiological index of beliefs at the same time that self-report identifications are delivered.

The Third Criterion: Nonawareness of a Belief

Fulfillment of the third criterion requires evidence that one of the two contradictory beliefs is not subject to awareness and in the present investigation requires demonstration that subjects are not aware of misidentifying voices. Showing that subjects are unaware of stimulus conditions, cognitions, and/or behavior has been particularly difficult in several areas of psychology except through the use of highly obtrusive measures (Martin, Hawryluk, & Guse, 1974; Nisbett & Wilson, 1977). Martin et al. (1974) wrote, "The most pressing methodological problem with the present studies is the one that plagues all studies of learning without awareness. There seems to be no entirely defensible method of assessing subject awareness after the experiment" (p. 604). To overcome this problem in the present study, two measures

of awareness of errors were taken. The first measure relies on postexperimental self-reports of whether subjects are aware of having committed errors. This measure is subject to the criticisms mentioned by Martin et al. (1974). The second measure, however, provides for this context a possible solution to the methodological problem, an unobtrusive index of awareness.

The unobtrusive index of awareness rests on the claim that consciously holding a belief that a voice is that of the self leads to differential consequences in subsequent responding than not being aware of such a belief. When subjects either correctly or incorrectly identify a voice as the self, their subsequent identification of the voice of another will be faster than their responses on other trials of voices of others. In the present study, trials of voices are arranged so that every presentation of the voice of self is followed by presentation of the voice of a stranger. If individuals correctly identify the self, awareness of this fact should make the next identification of the voice of another faster than responses to voices of another not preceded by identifications of self. This is the case because any difference in the physical properties of the voice consciously believed to be the self and those of the subsequent voice will aid in identifying the latter voice as that of another. If subjects are unaware that a given voice is the self, that is, if they commit a false negative error, they should not be faster in identifying the following voice than they are on remaining trials of voices of others. By the same argument, if subjects are not aware of committing false positive errors, that is of misidentifying others as self, they should be faster in identifying voices that immediately follow the false positive errors than in identifying voices that are not preceded by such errors. Comparisons of reaction times on trials following particular response types can thus provide an unobtrusive index of awareness.

The Fourth Criterion: Motivational Determinants

To fulfill the fourth criterion, it must be shown that misidentifications of self and others are motivated. This criterion is the most difficult to establish, and Experiment 1 is viewed as an initial step in this direction.

Previous studies have found that manipulations of self-esteem influence the aversiveness of self-confrontation (Davis & Brock, 1975; Duval & Wicklund, 1972; Gibbons & Wicklund, 1976). Likewise, it has been shown that measures of personality and psychopathology, particularly assessments of discrepant cognitions about the self, predict levels of psychophysiological reactivity during self-confrontation and changes in affect following the confrontation (Sackeim, Note 2). Given the hypothesis that subjects commit false negative errors in order to avoid aversive consequences of self-confrontation, it might be expected that subjects who commit such errors would score higher on measures of cognitive discrepancy than subjects who do not make these errors. However, this prediction can not be made because of the very fact that it is hypothesized that these subjects are engaging in self-deception. In line with Meehl and Hathaway (1946), we have argued that self-deception be viewed as a generalized response set that depresses measures of psychopathology (Sackeim & Gur, 1978, 1979). On the other hand, individuals who commit false positive responses (i.e., misidentifications of other as self), do so because they find self-confrontation pleasurable. The motivational determinants of these errors are opposite in direction to those of the false negative responses. It is expected that subjects who commit such errors will be low on measures of cognitive discrepancy that predict the aversiveness of self-confrontation.

To examine further the motivational contexts of misidentifications of self and others and to test the face validity of the claim that both these errors may be instances of self-deception, subjects were administered a questionnaire designed to assess individual differences in tendencies to engage in self-deception. It was predicted that subjects who committed either type of error would score higher on this measure than subjects who did not misidentify voices of self or others.

In summary, the following set of conditions should be fulfilled in order to demonstrate that misidentifications of voices of self and others are instances of self-deception: Psychophysiological reactivity to the voice of self is greater than reactivity to the voices of others, *regardless* of the correctness of identifications of voices. Subjects demonstrate that they are unaware of committing errors. Subjects who commit false negative responses or false positive responses, by and large, report that they are not aware of having made such errors. On trials following both true positive and false positive responses, subjects are faster in identifying voices, whereas no savings occur following false negative responses. Subjects who commit false positive responses are lower on measures of cognitive discrepancy than subjects who make no such responses. Subjects who commit either false positive and/or false negative responses are higher on a measure of individual differences in tendencies to engage in self-deception than subjects who commit no errors.

Method

Subjects

The subjects were 60 University of Pennsylvania undergraduate volunteers (30 male, 30 female). Only those students who had always lived in the northeastern United States were accepted as subjects.

Procedure

Subjects were given a set of personality and psychopathology inventories to fill out at home, with assurance that all results would be kept confidential. Appointments were made for returning the forms and participating in the experimental part of the study. Before arriving in the laboratory, subjects were informed only that they would be participating in a study on "voice discrimination and personality."

Upon arrival, subjects were taken to an experimental room, where samples of their voices were recorded. Subjects were seated in a chair so that their mouths were no more than one foot (30.5 cm) from a microphone. They were given a paragraph to read in a "normal speaking voice." Each subject read the same paragraph, taken from Kuhn (1962, pp. 124–125). This paragraph was chosen because pilot studies had indicated that subjects needed to pay careful attention to the text to read the paragraph correctly. This insured that few subjects would be paying close attention to particular intonations or phrasings.

After the voice sample was recorded, subjects were escorted to another room for electrode placement. GSR electrodes were placed on the volar surface of the middle phalanges of the second and third fingers of the nondominant hand. Subjects were then escorted to the experimental room.

Upon entering the experimental room, subjects were seated in a chair positioned in front of a small table. GSR electrodes were then connected to leads from a polygraph, which was in the room adjacent to the experimental room. When this was accomplished, the following instructions were read to subjects:

> We would like you now to participate in a rather straightforward task. I will soon place earphones on your head and we will play a tape for you. On the tape, there are 30 voices. There is a period of silence separating each voice. We want you to listen to every voice carefully. As soon as a voice starts, you should decide whether you think the voice is your own or that of a stranger. As soon as you have made a decision, you should press one of the six buttons, which tells us whether you thought the voice was your own or that of a stranger and how certain you are of this decision. The three buttons on the left (right) correspond to the choice of a stranger. The three buttons on the right (left) correspond to the self.[2] If you press Button 1 on either side, it means you are not very certain of your decision. If you press Button 2 on either side, it means you are somewhat certain of your decision, whether it be self or other. If you press Button 3 on either side, it means that you are very certain of your decision. Remember, press the button as quickly as you can, indicating your decision as to whether the voice was your own or not and how certain you are.
>
> Many of the voices you may hear will be on for very short periods. Do not be surprised. Your own voice may appear many times, a few times or even not at all. Press only one button per voice.
>
> In summary, all the task requires is that you listen to each of the 30 voices, make a decision as to whether each voice is that of a stranger or your own, and press one of six buttons telling us what your decision was, and how certain you were. You should do this as quickly as possible. Do you have any questions?

---

[2] The positions of "self" and "other" buttons on the left and right sides of the panel were randomized. Both sets of buttons were numbered from left to right.

Remember, please keep as still as possible and, in particular, do not move your left/right arm. There will now be a resting period of a few minutes before the task begins. I will put the earphones on you so that you can get used to them and, after a short while, come back and tell you when we are ready to begin.

After a period of 5 to 7 minutes, the experimenter returned to inform the subject that the tape was about to be run. During the experiment, subjects were monitored through a one-way mirror.

Each tape contained five groups of six voices, differing in temporal duration (2-, 4-, 6-, 12- and 24-sec periods). Ordering of the groups of voices was sequential, starting with the 2-sec voices. A period of silence, ranging from 20 to 40 sec (M = 30.00 sec) occurred before and after every voice. The position of voices on the tapes was fixed, with the self appearing once in each group (Voices 4, 10, 15, 24, and 28). Two voices of others were also repeated, each appearing once in each group. Male subjects were played tapes that contained male voices, and female subjects heard only voices of women. The tapes for the two sexes were identical in format. Each subject heard the same other voices, and all stimuli began with the third sentence in the recorded paragraph. The voices of others were provided by 17 male and 17 female undergraduates at the University of Pennsylvania. All had been born and lived continuously in the northeastern United States. They did not differ in age from the subjects in this study.

After subjects responded to the 30 voices, the electrodes were removed, and the subjects were taken to another room. They were then given a postexperimental questionnaire and the Self-Deception Questionnaire (SDQ; Sackeim & Gur, 1979). After these tests were completed, subjects were debriefed.

Apparatus

Master tapes were constructed so that silence periods, before and after the self, consisted of unrecordable leader tape. In this way, it was assured that voices would be present on the tapes for the exact temporal duration intended. No master tape was played on more than 11 occasions. The audiotape that was used in this study was a 1.5-mil professional mastering tape.

Silver/silver chloride electrodes, 11 mm in diameter, were used, with K-Y jelly serving as the electrolyte. Electrodes were plated prior to the beginning of the experiment. No pair of electrodes with a resistance greater than 250 Ω or with bias potentials greater than .5 mV was used (Edelberg, 1972; Venables & Martin, 1967). GSR was recorded on a Grass Model 7P polygraph, using a low-level direct-current preamplifier. For measurement of GSR, a constant current of 50 μA was passed.

All voices on the master tapes were recorded on the right channel. Simultaneous with the onset of the audio stimuli on the right channel was the onset of a 1000-cycle/sec sine wave signal on the left channel. These signals, of 150 msec duration, were recorded from a low-frequency function generator. Tapes were played in stereo, with subjects receiving in both ears only the right channel, through modification of a pair of headphones.

The onset of the sine wave signal triggered a voice-operated relay that simultaneously started a reaction time clock and registered on one channel of the polygraph. When subjects pressed one of the six buttons on the panel before them, the reaction time clock was stopped, and a light was lit in the control room indicating which button had been pressed.

Materials

Subjects were administered the Eysenck Personality Inventory (EPI; Eysenck & Eysenck, 1963) and a revised version of the Preexamination Questionnaire (PEQ; Liebert & Morris, 1967; Morris & Liebert, 1969, 1970).[3] The 10 items from the Neuroticism scale of the EPI used by Sackeim (Note 2) to measure cognitive discrepancy were again used in this fashion, along with the Worry scale of the PEQ. These inventories were administered before the experimental session.

The postexperimental questionnaire was concerned with whether subjects had hearing difficulties, how many times they thought they heard tape recordings of their own voices, whether they thought they committed either type of error, how certain they were when they first heard their own voices, what their reaction was to the voice, and how frequently in the past they had been exposed to recorded versions of their voices.

In addition, subjects filled out a questionnaire specifically constructed to measure self-deception, the SDQ. The questionnaire consists of 20 questions, all of which are meant to be psychologically threatening (e.g., Have you ever enjoyed your bowel movements? Have you ever doubted your sexual adequacy?). The questionnaire is answered on a 1 (not at all) to 7 (very much so) Likert-type scale, with scores of 1 or 2 on individual questions keyed as self-deceptions. Total SDQ scores (range = 0–20) are used in the analysis of results.

Results

Effects of Confrontation With Self and Others

In line with previous studies using self-confrontation procedures (e.g., Holzman et

[3] The PEQ, which is usually administered prior to examinations, was revised so that subjects indicated how worried and anxious they were about filling out the set of personality and psychopathology inventories.

al., 1966; Olivos, 1967; Sackeim, Note 2), subjects showed greater psychophysiological reactivity to the voice of self than of the voices of others. A three-factor (Self versus Other Voice Conditions × Sex × Trials) repeated measures analysis of variance on GSR change-in-conductance scores [4] revealed a significant effect of self versus other conditions, $F(1, 58) = 42.43$, $p < .001$. Sex was also associated with GSR reactivity, with females more reactive than males, $F(1, 58) = 4.41$, $p < .05$. There was a main effect of order of trials, $F(4, 232) = 4.47$, $p < .005$, as well as an interaction between the factor of self versus other voice conditions and that of order of trials, $F(4, 231) = 11.82$, $p < .001$. This interaction is illustrated in Figure 1.

As seen in Figure 1, the significant interaction indicates that psychophysiological reactivity in the other voice condition habituated with increasing number of trials, whereas reactivity to self did not habituate.

A similar analysis of variance with reaction time as the dependent variable revealed that reaction time was longer on trials of self compared to trials in which the voices of others were presented, $F(1, 58) = 18.84$, $p < .001$. There was no significant effect for sex, $F(1, 58) < 1$. The main effect of order of trials was significant, $F(4, 232) = 20.10$, $p < .001$, as was the interaction between this factor and that of self versus other voice conditions, $F(4, 231) = 14.68$, $p < .001$. This interaction is illustrated in Figure 2.

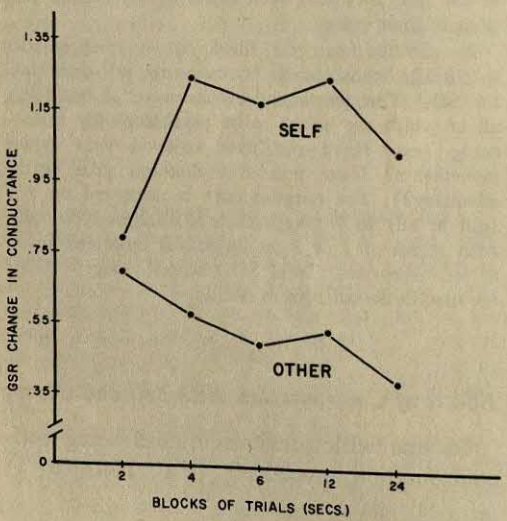

Figure 1. Galvanic skin response (GSR) reactivity (in micromhos) to voices of self and others as a function of block of trials. (Each block of trials increasingly differed in voice duration, as indicated on the abscissa.)

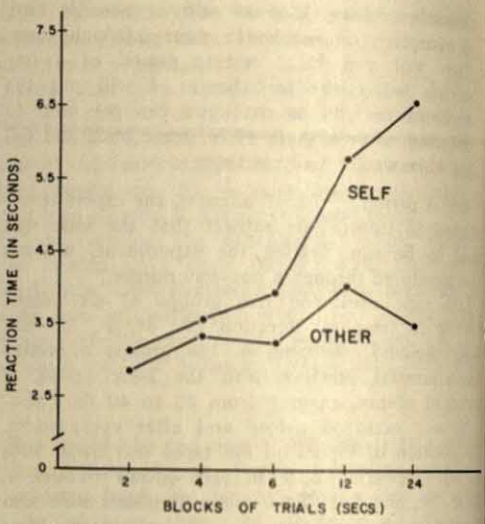

Figure 2. Reaction time to voices of self and others as a function of block of trials. (Each block of trials increasingly differed in voice duration, as indicated on the abscissa.)

Figure 2 suggests that the interaction occurred because the longer reaction time in later periods of the experiment was evidenced in identifications of self, but not in identifications of others.

Criteria for Ascribing Self-Deception

The first criterion: Holding two contradictory beliefs. To satisfy the first criterion for ascribing self-deception, it must be shown that GSR reactivity to the voice of self is as high when a subject denies that the voice is the self as when the subject correctly identifies the voice as the self. Likewise, it must be shown that GSR reactivity to the voices

[4] GSR reactivity scores are measured in units of microhmos (Edelberg, 1972). These scores are computed by converting resistance measures to change-in-conductance scores (i.e., $1000/R_2 - 1000/R_1$). R_2, in k-ohms, is the lowest level of resistance reached by subjects within 5 sec of voice onset. R_1, in k-ohms, is the level of resistance at voice onset.

of others is as low when a subject misidentifies others as self as when the subject correctly identifies others. As stated above, the motivational factors offered to account for false negative and false positive errors are opposite in direction. Subjects were therefore divided into four groups: subjects who made no errors ($n = 15$), subjects who made false negative errors only ($n = 14$),[5] subjects who made false positive errors only ($n = 18$), and subjects who made both false negative and false positive errors ($n = 13$). If subjects held contradictory beliefs when they misidentified voices, we would expect that in the group that committed false negative errors only, levels of GSR for true positive and false negative responses would not differ and would be higher than those for true negative responses. In the group that committed false positive errors only, levels of GSR for true negative and false positive responses should not differ and should be lower than levels of GSR for true positive responses. For the group of subjects who made no errors, levels of GSR should be higher on true positive as compared to true negative responses. Finally, the commission of both types of errors by the same subjects cannot be viewed as bona fide instances of self-deception, given the differing motivational factors that presumably produce each type of error. Accordingly, no expectations could be offered for this group.

Because of the significant interaction between self and other voice conditions and order of trials on GSR, subjects' change-in-conductance scores for all identifications had to be adjusted for the effect of this interaction.[6] To do that, for each subject, trial position was regressed on change-in-conductance scores separately for each voice condition. Adjusted scores, corrected for trial position, were obtained. The mean change-in-conductance scores, adjusted for trials, were computed within subjects for each response category. The results for the four groups of subjects are presented in Figure 3.

As expected, in the group that made no errors, GSR reactivity was greater for the voice of the self (true positive responses) as compared to the voices of others (true negative responses), $t(14) = 4.63$, $p < .001$, one-tailed. The crucial test of the self-deception hypothesis pertains to the behavior of subjects in the second and third groups. Consistent with this hypothesis, in the group whose only errors were false negative responses, levels of GSR were higher for both true positive and false negative responses compared to true negative responses, $t(12) = 2.91$, $p < .01$, one-tailed, and $t(12) = 2.14$, $p < .05$, one-tailed, respectively. Levels of GSR for true positive and false negative responses did not differ, $t(12) < 1$. The results for the group whose only errors were false positive responses were also consistent with the self-deception hypothesis. Levels of GSR were higher for true positive responses in comparison to both true negative responses, $t(17) = 4.05$, $p < .001$, one-tailed, and false positive responses, $t(17) = 2.20$, $p < .025$, one-tailed. False positive and true negative responses did not differ in levels of GSR, $t(17) < 1$. The results for the group that committed both types of error differ in pattern from the results of the two groups that committed one type of error. Therefore, it can not be claimed that subjects who committed both types of error held contradictory beliefs when the errors were being made. For this last group of subjects, none of the differences among the four response types reached statistical significance by two-tailed tests. The results for this group indicated that they were relatively insensitive in their self–other identifications on both verbal report and psychophysiological response measures.

In summary, those subjects who com-

[5] One subject, whose only errors were false negative responses, committed five such responses and did not make any true positive responses. Since the analyses of results bearing on the first criterion are within-subjects comparisons of mean change-in-conductance scores for the various response categories, the results for this subject were not included in these analyses.

[6] To determine whether GSR scores were also associated with the number of times subjects correctly identified voices as self, correlations were computed between number of identifications of self and mean GSR scores for all voices and separately for mean GSR scores for each response category. No associations were found.

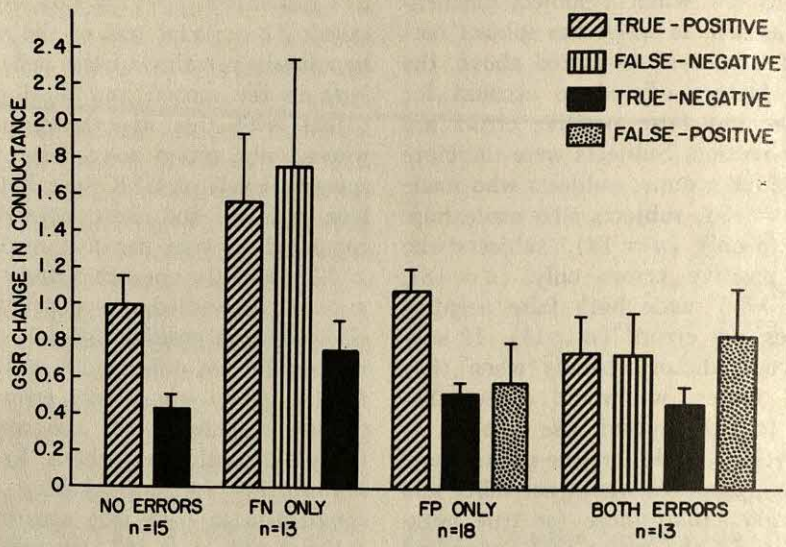

Figure 3. Mean galvanic skin response (GSR) reactivity (in micromhos), adjusted for order of trials, as a function of types of self-report identification for groups that committed no errors (NO ERRORS), false negative errors (FN ONLY), false positive errors (FP ONLY), and false negative and false positive errors (BOTH ERRORS).

mitted one type of error indicated by their GSR reactivity that when they misidentified voices, at some level of processing correct identifications had been made; these subjects, therefore, held contradictory beliefs.

The second criterion: Simultaneity of beliefs. Since the psychophysiological measurements were taken concurrent with subjects' identification of voices, the second criterion was satisfied by the very nature of the experimental procedure.

The third criterion: Nonawareness of misidentifications. Subjects' postexperimental reports as to whether they committed either type of error and their reports as to how many times they believed that the voice of self appeared on the tapes were in high agreement. Only 1 subject out of 27 who committed false negative responses reported having done so. On the other hand, of the 31 subjects who committed false positive responses, 16 claimed to have made such errors. Thus, on the basis of this obtrusive measure, virtually all subjects were not aware of having made false negative errors, whereas about half of the subjects who committed false positive errors lacked awareness of having made these responses.

The results for the unobtrusive measure of awareness were congruent with the findings from subjects' postexperimental reports. Within blocks of trials, reaction time on trials of other voices immediately following correct identifications of self (true positive responses) was first compared to reaction time for the remaining voices of others. This was done in order to establish that conscious belief that a voice was the self resulted in savings in reaction time on the subsequent trial. This was the case both for subjects who committed no false negative responses, $t(32) = 2.68$, $p < .01$, one-tailed, and for subjects who committed false negative errors, $t(25) = 2.12$, $p < .025$, one-tailed. Following false negative responses, however, reaction time was not faster on the subsequent trial of other, $t(25) = -1.91$, *ns*, indicating that savings occurred only after subjects expressed a conscious belief that a voice was the self.

A similar comparison was made between reaction time on trials that immediately followed misidentifications of voices of others as self (false positive responses) and reaction time on remaining voices of others, within blocks of trials (excluding trials of

other voices preceded by the voice of self). Here, the results were somewhat more complex. When this comparison was made for all subjects who committed false positive responses, faster reaction time on trials following false positive responses was not found, $t(30) < 1$. However, subjects were divided into two groups based on whether they were aware of committing false positive errors, as indicated by postexperimental self-reports. It was found that subjects who claimed not to be aware of making these errors were faster in their identifications following false positive responses, $t(14) = 2.25$, $p < .025$, one-tailed. Subjects who claimed to be aware of false positive errors were not faster on trials immediately following such responses than on remaining trials of voices of others. This pattern of results appears to buttress the validity of the unobtrusive measure of awareness. It also indicates that the lack of faster responding subsequent to false negative errors cannot be accounted for simply by the possible retarding effects of the commission of errors per se.

In summary, the results of both the obtrusive and unobtrusive measures of awareness converge in indicating that virtually all subjects who committed false negative responses were unaware of having made such errors. About half of the subjects who committed false positive errors were not cognizant of the fact.

The fourth criterion: The motivational aspect. In order to test the motivational account of misidentifications of voices, scores on our two measures of cognitive discrepancy were compared for subjects who committed two or more false positive errors and subjects who did not commit such errors. As expected, the groups differed on the Discrepancy scale taken from the EPI, $t(40) = 2.00$, $p < .05$, one-tailed, and on the Worry scale of the PEQ, $t(40) = 2.23$, $p < .025$, one-tailed. The group hypothesized to be actively seeking out self-confrontation (false positive responders) scored low on these predictors of the aversiveness of self-confrontation. Since this finding pertains only to one type of error, and in order to test the validity of the claim that both false negative and false positive errors can be instances of self-deception, SDQ scores were compared for subjects who had two or more misidentifications of either type and the remaining subjects. The results indicated that the former group had higher scores on this measure of individual differences in tendencies to engage in self-deception, $t(58) = 1.99$, $p < .05$, one-tailed.

These findings provide initial support for the motivational account of misidentifications of voices of self and others.

Consideration of Alternative Explanations

Independence of GSR and self-reports. The evidence presented in support of the first criterion can be interpreted as indicating that self-report identifications and identifications of voices as inferred from the GSR measure were relatively independent. In particular, when subjects misidentified voices by their self-reports, correct identifications could often be made on the basis of the GSR measure. This pattern of results is reminiscent of what early studies on subception were attempting to demonstrate (e.g., Lazarus & McCleary, 1951). In these studies, instances where correct identifications of stimuli could be attributed on the basis of GSR measures, while verbal reports were incorrect, were taken as evidence for subception. Eriksen (1956, 1958) criticized this interpretation of the findings by claiming that GSR and verbal reports were not independent response systems. He argued that GSR and verbal reports were substantially but imperfectly correlated and that the subception findings could be simply accounted for by the uncorrelated error term for GSR and verbal reports.

In order to examine whether the two response systems were independent, we first relied on Eriksen's method of computing the point-biserial correlation on mean GSR scores for trials of self when subjects were correct and incorrect in their self-reports. The same correlation was computed for trials of the other. Both correlations were not significant, $r_{pb}(25) = .03$ for voices of self, and $r_{pb}(30) = .15$ for voices of the other. These results indicate that whether subjects identified

voices as self or other had little influence on levels of GSR, and therefore, in this respect, the two response systems were independent.

Signal detection theory affords an opportunity to separate within response systems the effects of sensitivity and response bias in the identification of stimuli (Green & Swets, 1966). In the present context, such procedures would be particularly useful in establishing whether subjects who differ in the correctness of their self-reports do not differ in the sensitivity of their GSR in discriminating between voices of self and others. However, the small number of trials administered to each subject and the fact that the voice of self was presented to each subject on only five occasions preclude the application of standard signal detection methodology to these data, since separate measures of sensitivity and response bias can not be computed for each subject. Nonetheless, for descriptive purposes it might be useful to examine the sensitivity of GSR in groups of subjects pooled as a function of their self-report behavior.

In order to obtain confidence levels of the degree to which the GSR measure indicated judgments of self, percentages were computed for the GSR on each trial relative to the largest GSR within each block of trials. These percentages were categorized into 10% units. The number of trials of self and other voices falling within each unit was totaled for each subject. As in the analysis of results bearing on the first criterion, subjects were classified into the four groups on the basis of their self-report identifications. The data for subjects were pooled within groups to form essentially four types of perceivers.

Figure 4 presents receiver operating characteristic (ROC) curves for the four groups on the GSR measure. Cumulative probabilities of identifying the voice of another as self, $P(S/o)$, on the basis of GSR, are on the abscissa, and cumulative probabilities of identifying the voice of self as self, $P(S/s)$, are on the ordinate. A nonparametric measure of sensitivity, the area under the ROC curve, or $P(A)$ (McNicol, 1972), was computed for each group.[7] As can be seen in Figure 4, the sensitivity of the GSR was well above chance for all four groups of subjects. Subjects who did not commit any errors, $P(A) = .86$; subjects whose only errors were false negative responses, $P(A) = .82$; and subjects whose only errors were false positive responses, $P(A) = .85$, did not differ in sensitivity, whereas subjects who made both types of errors, $P(A) = .71$, showed lowered sensitivity in their GSR identifications of self and others. At least for the groups that identified voices in a manner congruent with the motivational account of misidentifications, these findings indicate that the self-report and GSR response systems were independent.

Effects of certainty of identifications. Another alternative account of the findings related to the first criterion might be stated as follows: Subjects have more difficulty and, therefore, are less certain when they identify their own voices as compared to voices of others. This greater uncertainty produces greater psychophysiological reactivity to voices of self. Furthermore, the differences in levels of GSR found for the four response categories may reflect differences in levels of certainty. In particular, the high level of GSR found when subjects commit false negative errors may indicate that subjects are particularly uncertain when such misidentifications are made. Of course, this account would have to posit that subjects are not uncertain when false positive errors are made.

---

[7] The most common measure of sensitivity derived from ROC curves is d'. However, to use d' it must be assumed that the distributions of signal (i.e., self) and of signal plus noise (i.e., other) are equal in variance and that both are normal—assumptions we are not entitled to make with the present data. The nonparametric measure of sensitivity, $P(A)$, does not require fulfillment of these assumptions. Furthermore, signal detection methodology usually enables one to separate the effects of sensitivity from the effects of response criteria or response bias on performance (Green & Swets, 1966). However, while the area under the ROC curve, or $P(A)$, is an acceptable nonparametric equivalent of d', there are no satisfactory nonparametric alternative measures of response criteria (McNicol, 1972). Therefore, response criteria effects were not examined in this analysis.

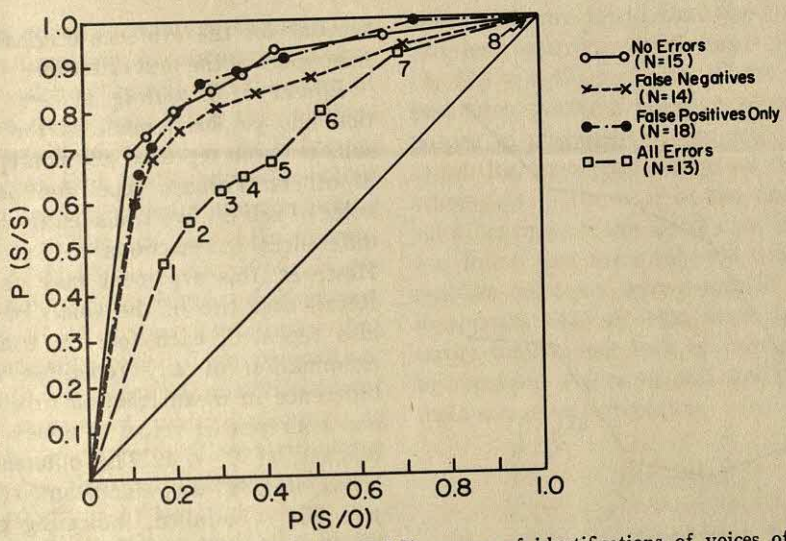

Figure 4. Receiver operating characteristic (ROC) curves of identifications of voices of self and others based on galvanic skin response (GSR) reactivity for groups committing no self-report errors, false negative errors, false positive errors, and false negative and false positive errors (all errors). [Points marked 1 correspond to the cumulative probabilities of hits, $P(S/s)$, and false alarms, $P(S/o)$, for GSR scores that were between 91% and 100% of the largest GSR within their respective block of trials. Points marked 2 correspond to the 81% to 90% interval; points marked 3 correspond to the 71% to 80% interval; points marked 5 correspond to the 41% to 50% interval. Because of low frequencies of occurrence, the data for the intervals 21% to 30% and 31% to 40% were combined and correspond to points marked 7. Likewise, points marked 8 correspond to the 0% to 20% interval.]

A three-factor (Self versus Other Voices × Sex × Trials) repeated measures analysis of variance on certainty judgments showed main effects for self versus other voices, $F(1, 58) = 14.49$, $p < .001$, and trials, $F(4, 232) = 7.92$, $p < .001$. Subjects were less certain of their identifications of the voice of self than of the voices of others, and certainty increased with trials (see Figure 5). Sex had no significant effect, $F(1, 58) < 1$, nor were there any significant interactions. These findings provide some support for the certainty account. There are a number of reasons, however, for rejecting this alternative explanation.

When certainty of identifications was included as a covariate in both analyses of GSR and reaction time, as a function of self versus other voices, sex, and trials, the patterns of results reported earlier were unaltered. In the analysis of the first criterion, the general finding was that levels of GSR did not differ for true positive and false negative responses on the one hand and for true negative and false positive responses on the other. For subjects who committed false negative errors, mean levels of certainty of identifications were compared for false negative and true positive responses. Subjects were neither more nor less certain when they made correct or incorrect identifications of their own voices, $t(25) < 1$. Therefore, the equivalence of levels of GSR despite differences in the correctness of self-reports for these responses cannot be attributed to differences in the certainty of identifications.

A similar comparison was made for levels of certainty on true negative and false positive responses for subjects who committed false positive errors. Here, it was found that when subjects correctly identified others, they were more certain than when they misidentified others, $t(30) = 8.12$, $p < .001$, two-tailed. Assuming that less certainty should result in greater psychophysiological arousal, this difference in certainty for the two response groups cannot account for their equivalence in low levels of GSR.

Finally, mean GSR for the four types of response might be compared at each level of certainty. Given that few subjects committed

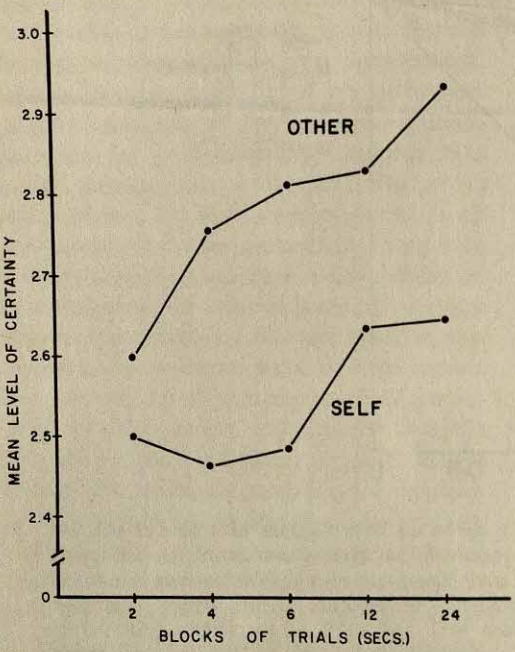

Figure 5. Certainty of identifications of voices of self and others as a function of blocks of trials. (Each block of trials increasingly differed in voice duration, as indicated on the abscissa.)

all four types of response and that it was impossible for any subject to make all four responses at each level of certainty, data had to be pooled across subjects. In Table 1, mean GSR is presented for the four types of self-report response at the three levels of certainty. The pooling of data across subjects, whereby subjects do not equally contribute to each cell of the table, precludes the use of standard statistical tests of significance of differences. However, inspection of Table 1 indicates greater GSR reactivity for true positive responses with the higher levels of certainty. There is no clear-cut relationship between GSR and certainty for false negative responses. For true negative responses, there is a trend for lower levels of certainty to be associated with greater levels of GSR. As in the case for true positive responses, higher levels of GSR for false positive responses were associated with higher levels of certainty. In sum, the trend of the results in Table 1, along with the previous analysis, disconfirms the alternative explanation that differences in the certainty of identifications account for the evidence originally presented in support of the first criterion.

Effects of repeating voices. No distinction has yet been made in the obtained results between repeated and nonrepeated voices of others. Perhaps repetition per se of the voice of self on five trials led to the significant differences in reactions to self and others. However, this argument may be discounted. Recall that two of the voices of others were also repeated, each for five trials, to allow examination of any repetition effects. The difference in mean reaction time on repeated and nonrepeated voices of others was not significant, $t(59) < 1$. The difference in mean levels of GSR was significant, $t(59) = 3.80$, $p < .001$, two-tailed, indicating greater habituation of GSR on repeated trials of other voices. Since this observed effect is opposite in direction to that which would account for the greater reactivity on trials of self, the combining of repeated and nonrepeated voices of others was justified.

Effects of previous exposure to playbacks of self. There may be a more parsimonious explanation of individual differences in rates of misidentifications of the self and others (rather than the motivational account offered here). People differ in their experience with tape playbacks of their own voices. The

Table 1
Mean GSR Reactivity Across Subjects for True Positive, False Negative, True Negative, and False Positive Responses for each of Three Levels of Certainty of Response

Response type	Certainty level	*n*	*M*	*SD*
True positive	High	48	1.18	.86
	Medium	25	.80	.70
	Low	13	.85	.54
False negative	High	14	.77	.80
	Medium	12	1.61	1.77
	Low	7	1.47	1.93
True negative	High	60	.53	.37
	Medium	48	.59	.37
	Low	26	.69	.61
False positive	High	11	.73	.60
	Medium	14	.86	.74
	Low	18	.47	.37

only previous study to examine the relationship between frequency of previous exposure to tape playbacks of the self and the rates of false negative responding found the relationship to be negative (Rousey & Holzman, 1967). However, that study, as well as other studies that have provided data concerning nonrecognition of the self (e.g., Holzman & Rousey, 1966; Holzman et al., 1966; Huntley, 1940; Olivos, 1967; Rousey & Holzman, 1967; Wolff, 1943), used procedures that tended to maximize rates of nonrecognition. This approach was deemed unadvisable for the present experiment, which attempted to minimize rates of nonrecognition attributable to factors other than self-deception. In this regard, the repetition of the trials of the self, the quality of the audio stimuli, the longer durations of voices, and the explicit instructions that the task was one of identification all served to minimize the difficulty of making self–other discriminations. The lowest rate of nonrecognition previously reported was in the Olivos (1967) experiment, where false negative responses constituted 45% of the responses to voices of self. In the present investigation, 18.7% of the trials of self involved false negative responses. The difference is maintained even when the percentage of false negatives on the first trial of self (31.7%) is compared with those of previous studies. Rates of false positive responding had not been reported in the literature. The rate of false positive responding in the present investigation was 3.8%. It can be concluded that the method employed in the present experiment succeeded in minimizing instances of nonrecognition.

To examine the association between exposure to playback of the self and rates of misidentifications, a one-way analysis of variance was performed for groups stratified for number of false negative responses (none, one, and two or more). This analysis indicated no association, $F(2, 56) < 1$. A similar analysis for groups stratified for number of false positive responses indicated that the groups did not differ significantly, $F(2, 57) = 2.74$, $.05 < p < .1$. However, when subjects who committed two or more false positive errors were compared to the rest of the sample, it was found that the former group had less experience with tape playbacks, $F(1, 57) = 5.47$, $p < .025$. These results suggest that overall frequency of previous exposure to playbacks of the self does not account for misidentifications of the self and others. As in the case of the analysis of results bearing on the third criterion, where it was found that some subjects who made false positive responses were aware of their errors, it appears that at least some false positive errors may reflect lack of previous exposure to recorded voices of self and are unlikely instances of self-deception.

Discussion

The results of Experiment 1 support the contention that there is a phenomenon that fits the concept of self-deception, since confirming evidence was found for fulfilling the four criteria for its ascription. When subjects misidentified the voices of self and others, they showed that at some level of processing correct identifications were made; their levels of GSR did not differ from those when they correctly identified voices, and therefore, they simultaneously held contradictory beliefs. Furthermore, subjects were not aware of misidentifying the voice of self and sometimes were not aware of incorrectly identifying voices of others. Finally, there is initial evidence that misidentifications of the voices of self and others are motivated. It was claimed that subjects who misidentify others as self are narcissistic in their self-regard and do not find self-confrontation aversive. In fact, they seek it out. These subjects scored low on measures that predict the aversiveness of self-confrontation. Subjects who misidentified either voices of self or others scored high on a measure of individual differences in tendencies to engage in self-deception.

Of the four criteria for ascribing self-deception, the results of the present study are least compelling in regard to satisfying the fourth criterion of motivation. The view that misidentifications of self and others are motivated requires further substantiation. The evidence presented so far is correlational in nature and does not fully address the question of whether

these misidentifications are purposeful, an issue implicit in attributions of motivation (Irwin, 1971). Furthermore, the results bearing on the fourth criterion pertain primarily to subjects who committed false positive errors. The claim that subjects who commit false negative errors do so because they find self-confrontation particularly aversive could not be examined. Additional evidence must be sought relating levels of cognitive discrepancy or self-esteem to misidentifications of both self and others in order to support the claim that these errors are motivated.

Experiment 2

Recent studies have shown that experimental manipulations of cognitive discrepancy influence selective exposure to the self. Duval, Wicklund, and Fine (cited in Duval & Wicklund, 1972, pp. 16–21) found that subjects who received prior negative false feedback about themselves departed from a room in which they were confronted with a mirror sooner than subjects who received prior positive false feedback or subjects who were not confronted with a mirror. Gibbons and Wicklund (1976) found that subjects whose self-esteem was enhanced by positive interaction with a female confederate subsequently spent more time listening to tapes of their own voices compared to subjects who experienced decreased self-esteem. Davis and Brock (1975) found that self-confronted subjects who received positive false feedback concerning a bogus test of creativity emitted more first person pronouns, when asked to guess English translations of foreign words, than subjects who received negative false feedback or subjects who were not self-confronted.

The results of these studies indicate that after experiences of negative feedback, self-esteem is lowered, and confrontation with the self becomes more aversive. On the other hand, positive feedback enhances self-esteem and makes self-confrontation less aversive. If the misidentifications subjects make when self-confronted are indeed motivated, one would expect subjects who have experienced failure or who have lowered self-esteem to demonstrate greater difficulty in making identifications of self. They should be slower in their reaction time on trials of self, they should be less certain in making such identifications, and, in particular, they should commit more false negative errors. Subjects who have experienced success should show less difficulty in identifying the self. Most importantly, they should commit a greater number of false positive errors.

Method

Subjects

The subjects were 60 University of Pennsylvania undergraduates (30 male, 30 female) who volunteered to participate in a study on intelligence and voice discrimination. All subjects had been born and lived continuously in the northeastern United States.

Materials and Procedure

When subjects reported for the study, they were informed that they would participate in two experiments, one of which required the recording of a speech sample. They were then asked to read the same paragraph that was used in Experiment 1, and their voices were recorded. Subjects were then greeted by another experimenter, who told them that they were to undergo an assessment of their intellectual capacities. They were informed that the purpose of that part of the study was to validate a short test designed to measure intelligence among college students. They were told that they would be presented with 15 multiple-choice synonym problems and that they must provide an answer to each problem within 30 sec of presentation. They were also informed that they would receive feedback concerning their performance on each question and on the test as a whole.

The experimenter then presented subjects with 15 synonym problems taken from the *Guilford-Zimmerman Aptitude Survey, Verbal Comprehension* (1953). Each problem was presented individually on an index card. The experimenter used a stopwatch to time subjects' responses. If a subject did not produce a response within 30 sec of presentation, the experimenter informed the subject that time had expired and requested an answer. Subjects were given feedback as to the correctness of each response, and when errors were made, subjects were told the correct answers. When the test was completed, subjects were told how many of the 15 problems they had answered correctly.

Subjects in the success condition were presented with the 15 easiest problems on the test, and subjects in the failure condition were presented with the 15 most difficult problems. Subjects were randomly assigned to the two conditions. However, final ac-

ceptance into the failure condition was contingent on subjects not succeeding on more than 10 of the 15 items. Similarly, final acceptance into the success group was contingent on correctly solving more than 10 of the problems. Five subjects who were initially assigned to the failure condition succeeded in solving more than 10 of the problems. The results of these subjects were dropped from the analyses reported below. None of the subjects initially assigned to the success group failed to reach the criterion for final inclusion in that group. In order to avoid any bias in assignment of subjects to groups, the results of four subjects, who were initially assigned to the success group and who had succeeded in solving all problems, were also dropped from the analyses. These four subjects were randomly chosen from all subjects in the success condition who had correctly solved the 15 problems. This procedure resulted in a final sample of 30 subjects in the failure group and 21 subjects in the success group.[8]

After completing the verbal problems, subjects were escorted to the experimental room, in which the voice identification task took place. Subjects were administered the Multiple Affect Adjective Checklist (Zuckerman & Lubin, 1965) and were then read the same instructions for the voice identification task as were used in Experiment 1, with the exception that subjects were not informed as to the number of voices that would appear on the tape. The tapes played to subjects contained 28 voices, each voice 4 sec in duration. The voice of the self appeared four times on each tape in Positions 6, 11, 19, and 24. A period of silence, ranging from 15 to 25 sec ($M =$ 20 sec) occurred before and after each voice. Male subjects were played tapes that contained male voices, and female subjects heard only voices of females. Each subject heard the same voices of others, and all voices began with the third sentence in the recorded paragraph. The voices of others were provided by 24 male and 24 female undergraduates at the University of Pennsylvania. All had been born and lived continuously in the northeastern United States. They did not differ in age from the subjects in this study.

After the tape was played, subjects completed a postexperimental questionnaire. Questions were designed to check the effect of the pretreatment manipulations. Respondents were also asked whether they had hearing difficulties, whether they had been aware of committing errors, what their reactions were to their own voices, and how frequently in the past they had been exposed to tape recordings of themselves.

The apparatus was identical to that used in Experiment 1, with the exception that GSR recordings were not taken.

Results

Manipulation Checks

The Multiple Affect Adjective Checklist (Zuckerman & Lubin, 1965) is scored on three dimensions: anxiety, depression, and hostility. As is seen in Figure 6, subjects in the failure condition were more anxious, $t(49) = 2.23$, $p < .025$, one-tailed; more depressed, $t(49) = 3.03$, $p < .005$, one-tailed; and more hostile, $t(49) = 2.03$, $p < .025$, one-tailed, than subjects in the success condition.

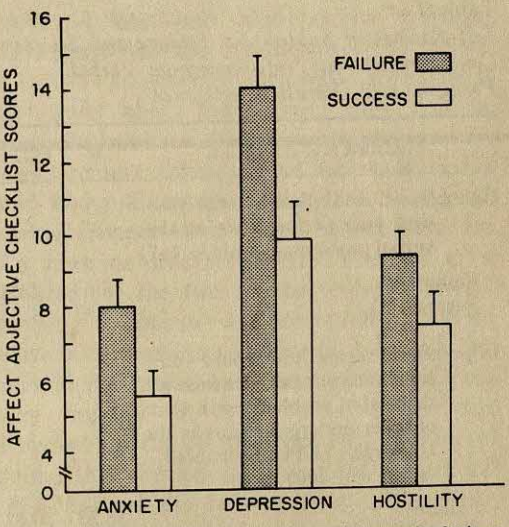

Figure 6. Effects of failure and success manipulations on Multiple Affect Adjective Checklist scores.

Subjects' evaluations of their performance on the verbal problems were assessed on the postexperimental questionnaire. As is shown in Table 2, subjects in the success condition were more pleased with their performance, $t(49) = 4.18$, $p < .001$, one-tailed, and rated their performance as comparing more favorably to that of other undergraduates, $t(49) = 3.92$, $p < .001$, one-tailed, than subjects in the failure condition. Ratings of degree of intelligence regardless of performance did not differ significantly between the two groups, $t(49) = 1.02$, *ns*.

---

[8] It could be argued that the five subjects initially assigned to the failure condition, by solving most of the difficult questions, had an experience of success and should have been reassigned to the success group. Were this to be done, there would be 30 subjects in each condition. With this assignment of subjects to conditions, the results are somewhat stronger than those to be reported below.

Table 2
Self-Ratings of Subjects in Failure and Success Conditions About Performance on Verbal Problems and Overall Intelligence

Measure and condition	*M*	*SD*
How pleased or displeased were you with your performance on the verbal problems? (scale = 1–7)		
Failure[a]	3.63	1.64
Success[b]	5.57	1.53
In percentile terms, how would you compare your performance on the verbal problems with that of other undergraduates at the University of Pennsylvania? (scale = 0–100)		
Failure[a]	58.33	20.83
Success[b]	81.62	19.89
How would you rate your overall intelligence compared to other undergraduates, regardless of your performance today? (scale = 0–100)		
Failure[a]	71.00	16.80
Success[b]	76.67	22.11

[a] $n = 30$.
[b] $n = 21$.

Effects of Success and Failure on Reaction Time and Certainty of Identifications

In line with the findings of Experiment 1, overall, subjects were slower in making identifications on trials of self than on trials of others. A three-factor (Success versus Failure × Self versus Other Voice Conditions × Trials) repeated measures analysis of variance on reaction time revealed a significant main effect for self versus other voice conditions, $F(1, 49) = 11.46$, $p = .002$. The main effect of order of trials was also significant, $F(3, 147) = 21.23$, $p < .001$. In Experiment 1, the order of trials was confounded with the duration of voices. The results of the present experiment indicated that when duration was held constant, subjects became faster in making identifications with increasing numbers of trials. The interaction between success versus failure and self versus other voice conditions was significant, $F(1, 49) = 4.24$, $p < .05$. As is seen in Figure 7, subjects in the failure condition, when compared to subjects in the success condition, were slower in making identifications on trials of self ($p < .05$). Subjects in the two groups did not differ in reaction time on trials of others. This finding indicates that the effects of failure did not generalize in slower reactions to all voices but resulted in retarded performance only on trials of self.

A similar analysis was performed on certainty of identifications. The main effects of self versus other voices, $F(1, 49) = 7.76$, $p < .01$, and order of trials, $F(3, 147) = 5.13$, $p < .005$, were significant. The interaction between success versus failure and self versus other voices did not reach significance, $F(1, 49) = 2.29$, $p > .05$. The results are illustrated in Figure 8. Figure 8 indicates that there was a trend for less certainty in identification on trials of self in the failure group and not in the success group.

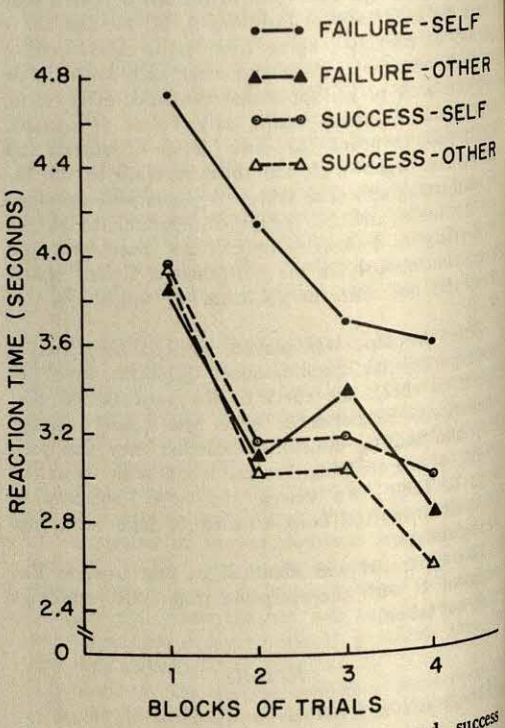

Figure 7. Reaction time of failure and success groups in identifying voices of self and others, as a function of block of trials.

Effects of Success and Failure on Errors of Identification

The rationale for Experiment 2 was based on the argument that errors made in identification of self and others are instances of self-deceptive acts and are therefore motivated. Accordingly, it was expected that subjects who had experienced failure would make more false negative errors, whereas subjects who had experienced success would commit more false positive errors. Eleven out of 30 subjects in the failure group had at least one failure to identify self (false negative error), while only 2 out of 21 subjects in the success group committed at least one false negative response. This effect was significant, $\chi^2(1) = 4.79$, $p < .05$. On the other hand, 13 subjects in the failure group made at least one erroneous judgment of self (false positive error), and 16 subjects in the success group made at least one false positive response. This effect was also significant, $\chi^2(1) = 5.44$, $p < .025$. In short, when people are made to feel good about themselves, they tend to "project" and see themselves in places where they are not. When people are made to feel bad about themselves they tend to "deny" seeing themselves in places where they are. To examine whether overall rates of error differed for the two groups, a degree-of-self-projection measure was computed by scoring each false negative response as -1, each correct identification as 0, and each false positive response as 1. Subjects' scores were summed for the 28 identifications, and it was found that the success group ($M = 1.19$, $SD = 1.68$) and the failure group ($M = -.07$, $SD = 1.81$) differed in types of errors committed, $t(49) = 2.47$, $p < .01$, one-tailed. Thus, the experimental pretreatment differentially influenced rates of types of misidentifications, thereby supporting the motivational account of these errors.[9]

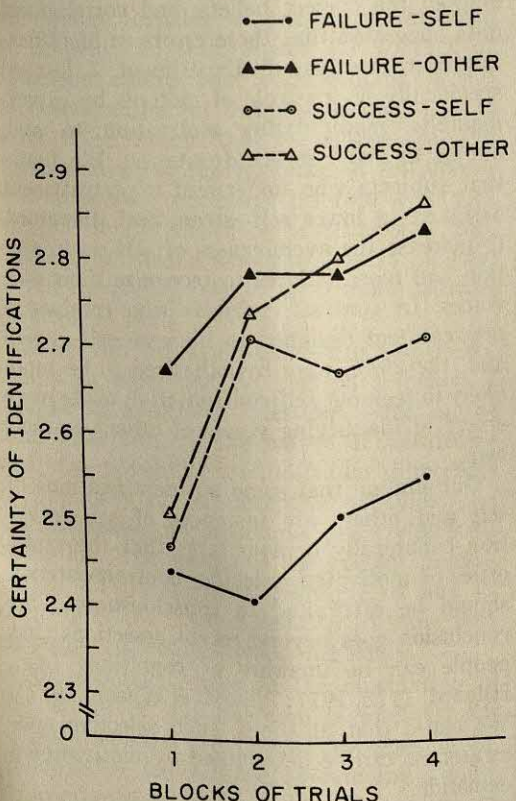

Figure 8. Certainty of failure and success groups in identifying voices of self and others, as a function of block of trials.

Reactions to Hearing the Voice of the Self

In the postexperimental questionnaire, subjects were asked to rate how much they enjoyed hearing their own voices and how unpleasant or pleasant they found their voices to be. Supporting the hypothesis that manipulations of cognitive discrepancy influence the aversiveness of self-confrontation, subjects in the failure condition ($M = 3.73$, $SD = 1.41$) tended to enjoy hearing the voice of self less than subjects in the success condition ($M = 4.33$, $SD = 1.04$), $t(49) = 1.63$, $p < .06$, one-tailed. The failure group ($M = 4.00$, $SD = 1.07$) also rated their voices as less pleasant than the success group ($M = 4.81$, $SD = 1.05$), $t(49) = 2.63$, $p < .01$, one-tailed.

[9] The obtrusive and unobtrusive measures of awareness of errors taken in Experiment 1 were also computed for Experiment 2. Replicating the results of Experiment 1, subjects were not aware of committing false negative errors, whereas some subjects were aware of having made false positive errors.

Discussion

We have argued that when people misidentify voices of self and others, they are engaging in self-deceptive behavior (Sackeim & Gur, 1978). In our view, part of the attribution of self-deception necessitates demonstrating that these errors are motivated. We claimed that individuals who are dissatisfied with themselves find confrontation with the self aversive. Identification of the self is more difficult for them, and they will avoid the aversive consequences of self-confrontation by failing to identify correctly the voice of self. On the other hand, we argued that individuals who hold themselves in high esteem do not find confrontation with the self aversive. Indeed, such individuals narcissistically seek out self-confrontation. Identification of the self is not difficult for them, and they demonstrate their preference for self-confrontation by identifying voices of others as self.

Previous studies have indicated that experimental manipulations of cognitive discrepancy or self-esteem influence selective exposure to the self (Duval & Wicklund, 1972; Gibbons & Wicklund, 1976). The principal measure used in these studies was the amount of time individuals engaged in exposure to the self. If our claim is valid that errors made in identification of the self and others are motivated, then we would expect manipulations of self-esteem to influence the difficulty of making identifications of the self and the rates of types of errors committed in identifying the self and others.

The results of Experiment 2 supported these predictions. Subjects who experienced failure were slower in making identifications of voice of self than subjects given pretreatments of success. The effects of the failure pretreatment did not generalize to identification of all voices, since the failure and success groups did not differ in the speed of their identifications of others. Furthermore, the two groups differed in the types of errors they committed. The failure group engaged in more false negative responding (misidentifications of self); the success group made more false positive errors (misidentifications of others). It could be argued that a number of seemingly "defensive" behaviors, such as self-serving biases in perception and memory, need not be determined by motivational factors (e.g., Greenwald, Note 3). However, the pattern of results presented here indicates that misidentifications of the self and others involve motivated distortions of reality.

General Discussion

This investigation was an attempt to demonstrate that a specific phenomenon, misidentification of the voices of self and others, is an instance of self-deception. In Experiment 1, we showed that when subjects made errors in identifying the voices of self and others, they provided evidence of simultaneously holding correct and incorrect beliefs as to the nature of the voices. We also found that subjects, for the most part, were not aware of holding the correct beliefs, and correlational data suggested that these errors in identification were motivated. Experiment 2 focused specifically on the role of motives by experimentally manipulating motivation to seek out or to avoid self-confrontation. We found that subjects who underwent a pretreatment designed to lower self-esteem and, therefore, to increase the aversiveness of self-confrontation had more failures to recognize their own voices. In contrast, subjects who received a pretreatment designed to increase self-esteem and, therefore, were hypothesized to be more likely to seek out self-confrontation made more errors of identifying voices of others as their own.

Our finding that some misidentifications of self and others are instances of self-deception collaterally demonstrates that the properties of motivated, selective nontransparency should be attributed to consciousness. This conclusion goes beyond recent assertions that people can be unaware of cognitions (e.g., Hilgard, 1976, 1977; Nisbett & Wilson, 1977). We claim that at times, such selective nonawareness can be determined by motivational demands.

A question that presents itself concerns the relationship of the concept of self-deception to the psychoanalytic notion of repression.

Certainly, the concept of repression also attributes a motivated, selective, nontransparent nature to consciousness. Since Freud (1914/1957) wrote that repression is "the cornerstone on which the whole structure of psychoanalysis rests" (p. 16), hundreds of psychological investigations have been interpreted as either propping up or tearing down this cornerstone. In a review of many of these investigations, Holmes (1974) concluded that there is no consistent experimental evidence supporting the existence of repression. However, it should be pointed out that the criteria for the ascription of self-deception may be necessary, but are certainly not sufficient, for the ascription of repression. The ascription of repression requires not only the claim that there is a motivated selective nonawareness of beliefs, it also requires the additional assertion that beliefs not subject to awareness are stored in an unconscious. The unconscious is a functionally independent control system, capable of purposeful influence on behavior. In this respect, the concept of repression entails that consciousness is not only nontransparent but also nonunitary. It is for these reasons that we believe that the demonstration of the existence of self-deception is logically necessary prior to a demonstration of the existence of repression and, further, that such a demonstration in the case of repression is likely to be a more arduous endeavor.

Given this initial evidence that self-deception is an experimentally real phenomenon, a number of additional questions come to the fore. They concern the nature of self-deception, the possibility of individual differences in frequency of self-deceptive behavior, and the processes and structures underlying self-deception. The results of the present investigation do not provide solutions to any of these questions, but in relation to some they do suggest directions for further study.

An important issue in the elucidation of the nature of self-deception is whether acts of self-deception are typical responses of individuals to, for instance, threatening stimuli, or whether they are specific and situation- or stimulus-bound. Our use in Experiment 1 of a paper-and-pencil questionnaire to assess individual differences in tendencies toward self-deception was predicated on the view that self-deception is not a stimulus-bound phenomenon but a generalized response set, or characteristic defense (Hilgard, 1949), the frequency of its use varying among people. In support of this view, we found that subjects who committed either false negative or false positive errors showed greater tendencies to deny psychologically threatening statements on the SDQ. Elsewhere (Sackeim & Gur, 1978, 1979), we have found that there are substantial negative correlations between SDQ scores and degree of self-reported psychopathology. The magnitude of the associations between SDQ and psychopathology measures is greater than that between standard lie scales and self-reported psychopathology. These findings support the contention of Meehl and Hathaway (1946) that "what is much more important, they (lie scales) are mainly directed at the sort of *conscious* falsehood which most writers have stressed, while ignoring the more subtle tendencies to self-deception which are probably of even greater importance in affecting scores" (p. 528). As a generalized response set, self-deception may influence behavior in contexts other than personality testing. For instance, Mischel (1974) argued that the "neurotic paradox" reflects a motivated attempt by individuals to keep specific ideas out of awareness and that all neurotic behavior is self-deceptive (cf. Abramson & Sackeim, 1977). The phenomena found in experiments on cognitive dissonance, self-serving biases in attribution, and studies of subjects' accounts of their behavior in obedience and conformity situations may be likewise interpreted in terms of self-deceptive acts. Since it may be possible to measure relative tendencies to employ self-deception, there is now an opportunity not only to examine individual differences in self-deception but also the influence of self-deception on broad ranges of behavior. As Jacques Rivière (cited in Fingarette, 1969) has suggested, "The discovery of a deceiving principle, a lying activity within us, can furnish an absolutely new view of all conscious life" (p. 1).

Television Viewing and Fear of Victimization: Is the Relationship Causal?

Anthony N. Doob and Glenn E. Macdonald
University of Toronto
Toronto, Canada

Previous findings have suggested that people who watch a lot of television are more likely to fear their environment than are those who report being less frequent viewers of television. From this simple correlation, previous authors have suggested that television causes people to overestimate the amount of danger that exists in their own neighborhoods. The present study attempted to replicate this finding and to determine if the apparent effect was due to a previously uncontrolled factor: the actual incidence of crime in the neighborhood. Respondents to a door-to-door survey indicated their media usage and estimated the likelihood of their being a victim of violence. Neighborhoods were chosen so as to include a high- and a low-crime area in downtown Toronto and a high- and a low-crime area in Toronto's suburbs. Pooling across the four areas sampled, the previous findings were replicated. However, the average within-area correlation was insignificant, suggesting that when actual incidence of crime is controlled for, there is no overall relationship between television viewing and fear of being a victim of crime. A multiple regression analysis and a canonical correlation analysis confirmed these findings.

A variety of social problems have been attributed to television viewing. It is said that television makes people more violent, that it lowers the level of literacy in the population, and that it distorts the viewer's perception of the world. There is little denying that the picture of reality that comes into people's homes is not an accurate reflection of their own society. That we learn from television, as we learn from every other medium, seems intuitively plausible independent of research results. Gerbner and Gross (1974, 1976a, 1976b; Gerbner et al., 1976), however, have suggested something even more serious than simple learning effects: that people not only learn factual information, such as the proportion of people involved in law enforcement, but that they generalize from the information that they get from television. In particular, Gerbner and his associates show that those who watch a lot of television are more likely to feel that they might be involved in some kind of violence during a given week than do those who watch relatively little television. This same pattern of results shows up in a variety of questions having to do with the viewers' perceptions of various aspects of the society in which they live. As Gerbner et al. (1976) point out, "Their heightened sense of fear and mistrust is manifested in their typically more apprehensive responses

We wish to thank Julian Roberts for his help and useful suggestions at all phases of this work and Bob Gebotys for his help in analyzing the data. The Metropolitan Toronto Police were very open and helpful to us in providing the data necessary for choosing our experimental neighborhoods. The research was supported by the (Ontario) Royal Commission on Violence in the Communications Industry, and a version of this study is published in Volume V of that commission's report. We wish to thank Mr. C. K. Marchant, the Director of Research of that commission, for his help and encouragement throughout all phases of the work. The data analysis was supported, in part, by funds provided to the Centre of Criminology, University of Toronto, by the Ministry of the Solicitor General, Canada.

Requests for reprints should be sent to Anthony N. Doob, Department of Psychology, University of Toronto, Toronto, Ontario, Canada M5S 1A1.

to questions about their own personal safety, about crime and law enforcement, and about trust in people" (p. 9).

Obviously, heavy television viewing is not independent of other social factors. Gerbner and Gross (1976a) have found that "heavy viewing is part and parcel of a complex syndrome which also includes lower education, lower mobility, lower aspirations, higher anxieties, and other class, age, and sex-related characteristics" (p. 191).

Because of the problem of confounding variables, Gerbner has been careful to break down his data on various other characteristics of television viewers such as age, sex, educational level, news reading, news magazine reading, prime-time viewing, and viewing or nonviewing of TV news. The notable finding in all of these comparisons is that although there may be main effects of some of these other characteristics, in all cases, heavy viewers are more likely than light viewers to feel that they might be involved in some violence.

No list of possible confounding variables can be complete. The worry of any researcher doing correlational research and wishing to make a causal statement is that some other variable would, in fact, account for the effect apparently demonstrated. We felt that there is one quite plausible factor that might account for the correlation between viewing and fear of violence: People who watch a lot of television may have a greater fear of being victims of violent crimes because, in fact, they live in more violent neighborhoods.

The study that this explanation suggests, then, is quite obvious: A survey of the television viewing habits of people and their perception of being involved in violence should be performed in both high- and low-crime neighborhoods. Pooling across neighborhoods, we should be able to replicate Gerbner's and his associates' findings; within neighborhoods, however, the effect should be substantially reduced or eliminated.

Method

For purposes of efficient distribution of resources, the Metropolitan Toronto Police have divided Toronto into approximately 210 patrol areas. The size of these patrol areas varies not only as a function of the resident population but also as a function of the number of calls of all types that the police receive in the area: Busy areas thus tend to be smaller in terms of the size of the population served and in terms of geographic area. The police identified for us the 10 patrol areas with the highest number of reported assaults and woundings and the 14 areas with the lowest number of reported assaults and woundings for the 7-month period ending 2 months before the beginning of the survey. From these data, four geographic areas, approximately equal in size, were chosen. Two (one within the city of Toronto, the other suburban) were high in reported crime; two (one city, one suburban) were low in reported crime. It is difficult to estimate the exact rates of crime for the four areas. However, very rough estimates would suggest that the rates of assaults and woundings per 100,000 resident population for the 7-month period for the four designated areas would be the following: high-crime city, 614; low-crime city, 8; high-crime suburb, 195; low-crime suburb, 6. It must be emphasized that these are very rough figures: The low-crime areas each had only two reported assaults (and no woundings) for the entire 7-month period; hence the estimates are bound to be unstable. There were eight patrol areas constituting the high-crime city area; one patrol area was sampled for the high-crime suburban area and two each for the low-crime areas.

Obviously, the four areas differ considerably on a large number of social variables other than reported crime rates. The high-crime city area contains a portion of the downtown commercial/entertainment district of the city, the largest block of public housing in the metropolitan area, and much of the poorest portion of the population. The low-crime city area is largely expensive, single, detached houses and is one of the more exclusive residential areas. The high-crime suburban area contains a high concentration of low-rise public housing and is generally fairly poor. The low-crime suburban area is mostly single, detached, middle-class housing.

Random households were chosen within each of these areas. Interviewers, employed by a commercial survey company, did a door-to-door survey. The person who answered the door was asked to list all of the people over 18 years of age living in the household. One of these people was then chosen at random by the interviewer. If this person could not be interviewed at that time or at some mutually acceptable time, the interviewer went on to the next randomly chosen household, and the procedure was repeated. The effect of this selection procedure was an oversampling of women (70.5%) and, presumably, a general oversampling of those who spend much of the time at home. Although this effect would be unfortunate if one were interested in estimating population values for the measures that were taken, it was less relevant in our study, where we were interested in the relationship between television viewing and fear of criminal victimization.

Table 1
Mean Fear-of-Crime Factor Scores for Each of the Sampled Areas

Area	City		Suburb	
	M	*n*	*M*	*n*
High crime	.28	83	.15	69
Low crime	−.34	71	−.13	77

Note. The higher the number, the more fear.

Respondents were first asked to indicate those programs that they had watched during the previous week. According to our interviewers, very few people had any difficulty in doing this. They were then asked to complete a 37-item fixed-alternatives questionnaire. This questionnaire consisted of six questions dealing directly with the person's estimate of his or her own likelihood of being a victim of a crime; four questions dealing with estimates of the likelihood of particular groups of people being victims; four questions dealing with the perception of crime in general being a problem and there being a need for more police personnel; two questions dealing with the necessity to arm oneself; eight questions of a factual nature dealing with crime; three questions dealing with society's response to crime; four questions dealing with the respondents' view of Toronto with respect to crime; three questions dealing with the respondents' prediction of their response to a request for help; and three questions dealing with media usage. The whole interview took approximately 45 minutes on the average.

For purposes of analyzing the types of television, we decided to use the number of programs watched as an index of total viewing. In addition, programs were coded by a research associate into violent and nonviolent types before the tabulation of the other data. It should be pointed out that this last measure is, necessarily, somewhat subjective. However, as will be seen, this turns out not to be a serious problem in understanding the results.

Results

In order to reduce the number of measures to a somewhat workable number, a factor analysis was performed [1] on the 34 opinion questions. Using a varimax rotation, only one factor accounted for a substantial amount of the common variance. The percentages of the common variance accounted for by the first 4 of the 11 factors were 35.9%, 12.5%, 10.8%, and 8.4%. The questions that loaded highest on the first factor are shown in Table 4; they were the six questions related to the respondents' estimates of their own chance of victimization, two of the questions dealing with the chances of victimization of particular groups, and one of the questions dealing with crime as a general problem. Generally speaking, it seems fair to label this factor "fear of crime." Each of the next three factors had substantial loadings from only one or two questions.

As one would expect, the residents of the four areas differed significantly on their overall fear of crime. The average factor scores for the four areas are shown in Table 1. Analysis of variance on the factor scores revealed a main effect for high-/low-crime area that was highly significant, $F(1, 296) = 17.79$, $< .01$. Neither the city/suburb effect nor the interaction was significant. It is clear, then, that people who live in high-crime areas, are, in fact, more afraid.

The four areas sampled also differed on their exposure to the various media. Table 2 presents these data. Overall, people in high-crime areas watched more television and, generally speaking, tended to watch more violent television. Although there were interactions between the two factors on these two measures, for the purposes of this article, these interactions are not very important. As one might expect, since the areas differed on so many dimensions, there were also effects on self-report of exposure to radio news: People living in low-crime areas tended to report listening to radio news more frequently. Furthermore, the reported frequency of newspaper reading was higher in low-crime areas and in the city.

Gerbner and his associates (Gerbner & Gross, 1974, 1976a, 1976b; Gerbner et al., 1976) do not directly present measures of association between the total amount of tele-

[1] The input for the factor analysis consisted only of those 300 respondents (of the total of 408) who answered every question. Most of the other 108 respondents failed to answer only a few of the questions. The proportion of complete questionnaires varied somewhat from area to area. The numbers of complete/total questionnaires are as follows: high-crime city, 83/119, or 70%; low-crime city, 71/118, or 60%; high-crime suburb, 69/85, or 81%; low-crime suburb, 77/86, or 90%.

Table 2
Media Usage for the Four Areas

Medium	High-crime area		Low-crime area		*F* value		
	City (119)	Suburbs (85)	City (118)	Suburbs (86)	High/low crime	City/ suburb	Interaction
Total TV	36.25	31.71	18.89	25.03	25.21**	<1	4.98*
TV violence	6.97	3.73	2.11	3.33	23.25**	2.72	18.11**
TV news	3.07	2.99	3.72	3.74	2.83	<1	<1
Radio news	5.07	4.96	5.44	5.37	9.79**	<1	<1
Newspaper reading	4.78	4.58	5.26	4.80	6.89**	6.01*	<1

Note. For TV viewing, numbers refer to mean number of programs watched during the previous week. The other measures are mean values on a scale where 1 equals never and 6 equals daily. *n*s are in parentheses.
* $p < .05$.
** $p < .01$.

vision viewed by their respondents (in response to the question "How many hours a day do you usually watch television? Please include morning, afternoon, and evening") and their fear of being a victim of a violent crime (in response to the question "During any given week, what are your chances of being involved in some type of violence—about a 50–50 chance, about a 1-in-10 chance, or about a 1-in-100 chance?"). However, estimating from the data that are presented in the various reports, we calculated a phi coefficient of .13 and a contingency coefficient of the same value.

Looking at our data, then, we calculated the (Pearson) correlation between our fear-of-crime factor scores and our various measures of media usage. These correlations are presented in the first column of Table 3. It is quite clear that the basic effect is much the same as that found by Gerbner and his associates: Across the four areas, those who watched the most television (or violent television) tended to be those who were the most afraid. However, the effect *within* area is not quite so simple: Although the effect would appear to hold in the high-crime area of the city, it tended to disappear for the other areas. Indeed, the average correlations (last column of Table 3) indicate that there is essentially no relationship between media usage and fear of crime when the effect of neighborhood is removed. We have suggested that the artifact that created the first two correlations in the first column might be labeled "actual incidence of crime." However, in terms of the focus of this article (the relationship of media usage to fear of crime), the

Table 3
Correlations Between Media Usage and Fear-of-Crime Factor Scores for all Subjects (Pooled), for Each of the Four Areas, and for the Average of the Four Areas

Medium	Pooled across all areas	High crime		Low crime		Average correlation
		City (83)	Suburb (69)	City (71)	Suburb (77)	
Total TV	.18**	.24*	.16	.06	−.09	.09
TV violence	.18**	.22*	−.03	.14	−.04	.07
TV news	.05	.14	−.04	.05	.06	.05
Radio news	.05	.18	−.09	−.02	.21	.07
Newspaper reading	−.07	−.20*	−.14	.09	.15	−.03

Note. Positive correlations indicate more fear associated with higher media usage. *n*s are in parentheses.
* $p < .05$.
** $p < .001$.

Table 4
Fear-of-Crime Questions and the Correlations Between Responses to Each Question and Total TV Viewing and TV Violence for the Four Areas Pooled and the Average of the Four Areas Calculated Individually

Question	Total TV		TV violence		High TV viewing associated with
	Pooled	Average within area	Pooled	Average within area	
1. To what extent are crimes of violence a serious problem in your neighborhood? (399)	.07	−.02	.16*	0	Serious problem
2. What do you think the chances are that if you were to walk alone at night on the residential streets of your neighborhood each night for a month that you would be the victim of a serious crime? (391)	.18*	.10*	.19*	.05	High probability (1 in 10)
3. If a child were to play alone in a park each day for a month, what do you think the chances are that he would be the victim of a violent crime? (382)	.12*	.02	.22*	.12*	High probability (1 in 10)
4. If you were to walk by yourself in a park close to your home each night for a month, what do you think the chances are that you would be the victim of a serious crime? (391)	.10*	.02	.14*	.04	High probability (1 in 10)
5. What do you think the chances are that an unaccompanied woman would be the victim of a violent crime late at night in a Toronto subway station? (389)	.10*	.04	.09	.04	High probability (1 in 10)
6. What do you think the chances are that you, one of your family, or one of your close friends might be the victim of an assault during the next year? (385)	.13*	.02	.12*	−.02	High probability (1 in 10)
7. How likely do you think it is that you or one of your close friends would have their house broken into during the next year? (405)	−.04	−.07	.01	−.01	Extremely unlikely
8. Do you ever decide not to walk alone at night because you are afraid of being the victim of a violent crime? (402)	.05	.06	−.04	−.04	Very often
9. Is there any area around your home (i.e., within a mile) where you would be afraid to walk alone at night? (403)	.12*	.05	.02	−.06	Yes

Note. *n*s of respondents for each question are in parentheses.
* $p < .05$.

name given to this variable is unimportant: When the effect of neighborhood is removed, the "effect" of television is reduced to almost nothing.

Clearly, however, the artifact (whatever it is called) measures in only the crudest way the amount of crime that a person is exposed to. For example, a person living in one part of what we have labeled as a high-crime section of the city might, in fact, be quite safe: The crimes might well be in a different section of that patrol area. However crude the measure might be, the size of the correlations does drop dramatically.

It should be pointed out that correlations are responsive to effects other than the strength of the relationship between two variables. In particular, as McNemar (1962) points out, "the magnitude of the correlation coefficient varies with the degree of heterogeneity (with respect to the traits being correlated) of the sample" (p. 144). Given that we have divided our overall sample (into the four areas) in a manner that clearly relates to both of the variables (see Tables 1 and 2), this curtailment of the variance could be a problem. It turns out, however, not to be a serious problem in this case. The ratios of the standard deviations of the "curtailed" distribution (average of the four areas' standard deviations) to the uncurtailed distribution (standard deviation for the four areas pooled) are .965, .917, and .844 for the factor scores, total TV viewing scores, and TV violence scores, respectively. McNemar (1962) indicates that "formulas for 'correcting' for double curtailment are not too satisfactory" (p. 145). However, correcting for the curtailment of the range for the most curtailed distribution (TV violence) would only raise the average correlation between fear and amount of violent TV watched (averaged across the four areas) from .07 to .09.

The data look very much the same when analyzed question by question. The nine questions with the highest weight on the first factor of the factor analysis are shown in Table 4. In addition, the overall correlations for all subjects pooled across areas are shown in the first column (for each question with total TV viewing) and the third column (for the responses to each question and violent TV). All of the significant correlations are in the direction consistent with the Gerbner (Gerbner & Gross, 1974, 1976a, 1976b; Gerbner et al., 1976) findings (i.e., more TV associated with higher likelihood of victimization, etc.). Generally speaking, it is clear that the correlations tend to decrease substantially in size when they are run within the four areas and then pooled.

Table 5
Stepwise Multiple Regression Summary[a]

Variable	R when entered[b]	F when entered[c]	F in final equation[d]
High/low crime	.234	17.234**	16.704**
City/suburb	.235	.186	.051

[d] Equivalent to a test of the null hypothesis that the beta for this measure in the final equation involving all nine variables is zero.
* $p < .05$ ($df = 1$ and ≥ 290 for all Fs).
** $p < .01$.

An alternative method of analyzing these data is in a stepwise multiple regression analysis using the fear-of-crime factor scores as the criterion and various other social and media exposure data as predictors. In order to control for neighborhood, this was entered first into the regression equation (coded as three variables: high/low crime, city/suburb, and their interaction). Next, two subject characteristics, sex and age, were entered, since both of them related to the fear-of-crime measure. (Not surprisingly, women and older people reported higher levels of fear than did men and younger people.) After these more "basic" variables had been entered, total TV viewing and TV violence were entered. Finally, the frequency of listen-

[a] Using Wilks' lambda. Using the method of the greatest characteristic root, the third pair of canonical variates is not significant. For a discussion of this problem, see Harris (1976).

ing to radio news and newspaper reading were entered into the equation.

The results are shown in Table 5. It is clear that after the subject characteristics had been entered, the media questions had no significant predictive value. Most relevant to the Gerbner results is of course the lack of importance of total TV viewing when it first entered the equation.

Finally, a canonical correlation analysis was done, using the nine fear-of-crime questions (see Table 4) as the criterion set and the same nine variables as in the multiple regression analysis (see Table 5) as the predictor set. Three significant canonical correlations were found. The variates associated with these correlations are shown in Table 6.

The first pair of canonical variates suggests that those who do not see crimes of violence as a problem in their neighborhood (Question 1), who do not think that a child playing alone in a park is in danger (Question 3), and who do not think that they themselves are likely to be victims of an assault (Question 6), but who are afraid that their houses will be broken into (Question 7) and who do not walk alone at night (Question 8) tend to be females living in low-crime (city) areas.

The second pair of canonical variates appears to indicate that people who have areas near them that they will not walk in at night (Question 9) and who fear walking alone at night (Question 8), but who do not think that they will be victims of a violent crime (Question 6), tend to be females living in high-crime (city) areas who listen to a lot of radio news.

The third set of variates suggests that those who think that unaccompanied female subway riders (Question 5) and children playing alone in parks (Question 3) are vulnerable to attacks, but who themselves do not feel vulnerable (Question 6) and do not worry

about walking alone at night (Question 8), since their neighborhoods are safe (Question 1), tend to be suburban (low-crime area) residents who watch a lot of violent TV and do not listen to radio news.

The total amount of television watched did not seem to be important, and the amount of violent television watched entered into the interpretation only in the third canonical variate. Even in this case, it appears that the amount of violent TV watched related positively to the perceived vulnerability of particular groups (female subway riders and children playing alone in parks) but negatively to the perceived likelihood of the respondents themselves being victims of violent crime.

In summary, then, looking at these data from three somewhat different points of view, it appears that the amount of television watched did not relate to the amount of fear a person felt about being a victim of crime when other, more basic variables were taken into account.

Other Findings

As indicated earlier, we asked 25 other questions. Most of these questions related, directly or indirectly, to the respondents' views of the nature and frequency of crime or violence around them. In 14 of the questions, there was a significant relationship (pooled or calculated individually and then averaged) between TV viewing and the response to the question. The questions and the relationship of each question to TV viewing are shown in Table 7. What is noteworthy about these correlations is that there is generally not a substantial drop when the correlations are computed within area and then averaged (column 2 of Table 7). Thus, it appears that the relationship between total TV viewing and responses to these questions is not mediated by the area in which the respondent resides. These were the only other questions that correlated with TV viewing, and, at least from our point of view, they are qualitatively different from those that were large contributors to the "fear index" (see Table 4). Because it is not of central interest to this study, we did not look at other possible factors that might account for the correlations that we have presented.

Discussion

A number of things are reasonably clear from these data. First of all, the basic findings of Gerbner and his associates (Gerbner & Gross, 1974, 1976a, 1976b; Gerbner et al., 1976) are replicable: People who watch a lot of television are more likely to indicate fear of their environment. It is equally clear, however, that this relationship disappears when attempts are made to control for other variables, including the actual incidence of crime in the neighborhood. Thus, it would appear that television itself is not likely to be a direct cause of people's fear of being victims of crime.

Although clearly at the level of speculation, it is interesting to note that Gerbner's (Gerbner & Gross, 1974) own data on this issue were collected by telephone interview in four cities: Philadelphia, Chicago, Los Angeles, and Dallas. One can assume that there exists in these cities some variability in the dangerousness of different neighborhoods. Since households for that survey were selected randomly from telephone books, it seems reasonable to expect that neighborhoods differing in actual dangerousness would be included from each city. This variation could be sufficient to produce the apparently small correlation that Gerbner found. More interesting, however, is the possibility that for some unspecifiable reason, the relationship only holds in high-crime areas, or in high-crime cities in particular. As shown in Table 3, we, too, got significant correlations within the high-crime area of the city of Toronto. One possible admittedly post hoc explanation for this result is that television violence in the form of police shows and so forth deals mostly with high-crime city neighborhoods. It is possible that people outside of such areas do not feel that the violence on television has any relevance for them; hence, there is no relationship between the amount of television watched and the perception of the likelihood of being a victim.

Table 7
Questions Associated Significantly With TV Viewing: Correlations Between Responses to Each Question and Total TV and TV Violence for the Four Areas Pooled and the Average of the Four Areas Calculated Individually

Question	Total TV		TV violence		High TV viewing associated with
	Pooled	Average within area	Pooled	Average within area	
10. Would you imagine that you would be more likely to be seriously harmed by someone you knew previously or by a complete stranger? (400)	.12*	.09*	.04	.06	Previously known
12. How dangerous do you think it is for a female driver of a car to pick up a male hitchhiker who is a stranger? (404)	.09*	.06	.06	.06	Dangerous
13. Do you think that it would be a good idea to spend more money on police patrols of your area of the city? (403)	.11*	.06	.12*	.08	Definitely yes
17. Do you think that it is useful for people to keep firearms in their homes to protect themselves? (405)	.31*	.20*	.25*	.11*	Definitely yes
20. Should women carry a weapon such as a knife to protect themselves against sexual assault? (405)	.18*	.17*	.19*	.18*	Definitely yes
21. Some people have suggested that one way to reduce the incidence of violent crime is to encourage people to stay away from areas thought to be high in crime. Do you think that this is a good way of dealing with the problem of crime? (403)	.09*	.07	.09*	.06	Definitely yes
22. What proportion of murders in Toronto do you think are committed by people who could be classified as mentally ill? (381)	.11*	.10*	.08*	.09*	High proportion
23. Approximately what proportion of assaults in Toronto are directed against members of racial minorities (i.e., nonwhites) by whites? (359)	.10*	.12*	.09*	.11*	High proportion
24. What proportion of serious assaults in Toronto do you think are carried out by nonwhites? (364)	.08	.11*	.08	.12*	High proportion
25. How many murders do you think took place in metropolitan Toronto during 1975? (372)	.17*	.16*	.16*	.13*	Large number

Table 7 (*continued*)

Question	Total TV		TV violence		High TV viewing associated with
	Pooled	Average within area	Pooled	Average within area	
26. During the last 5 years, how many people do you think were murdered in the TTC subway? (384)	.15*	.12*	.09*	.08*	Large number
31. If you were walking alone on a residential street at night and someone asked you for directions, would you stop and give him the directions? (404)	.10*	.11*	0	0	Definitely not
32. If a person were to have an epileptic seizure on the street in front of you, how likely do you think most people would be to help? (405)	.10*	.07	.08	0	Very likely
33. If, in the middle of the night, a stranger knocked on your door and asked to use your telephone to call someone to help him start his car that had apparently stalled on your street, which of the following would you be most likely to do? (404)	.11*	.12*	.05	.03	Not help

Note. *ns* of respondents for each question are in parentheses.
* $p < .05$.

The second general point that should be made about our data is that although the correlation between TV viewing and fear dropped off when neighborhood was used as a controlling factor, this same factor did not eliminate the relationship between TV viewing and other factors (see Table 7). It is possible that the questions listed in Table 7 are, in fact, related to television viewing because they deal with matters of a more factual nature than the questions having to do with the person's own level of fear. Thus, television may well act as a source of information with regard to questions of fact, whereas it does not change people's views of how afraid they should be.

Retrieval Selectivity in Memory-Based Impression Judgments

John H. Lingle
Livingston College, Rutgers—
The State University

Thomas M. Ostrom
Ohio State University

Judgments about others are often based on memory for information about the persons being judged. Three studies are reported that use decision time to determine what information subjects selectively recall when they make memory-based person judgments. Each study employed a sequential judgment paradigm in which a subject first made an impression judgment about a person on one dimension while stimulus information was continuously available. Immediately thereafter, the subject made a second judgment about the same person on a different dimension without the stimulus information being available. It was concluded that subjects' memory-based judgments were based on memory for their first impression judgments combined with a selective memory search for negative stimulus information.

In recent years a great deal of impression formation research has been directed towards describing how people integrate multiple information items when they make a single person-impression judgment. Such research has dealt almost exclusively with stimulus-based judgments. These are judgments that derive from descriptive information that the experimenter provides immediately prior to, or simultaneously with, the judgment that is made. In most day-to-day situations, however, the judgments that people make about others are memory-based. That is, rather than being derived from a set of presented factual information items, the judgments are based on a selective sampling of information from a cognitive representation of the person that the perceiver has built up and stored in memory. In order to understand the majority of interpersonal judgments that people make, it is necessary to understand how (and what kind of) information is sampled from memory when memory-based interpersonal decisions are made. To examine this question, this article reports three experiments that investigated the degree to which an initial stimulus-based judgment that a person makes about a stranger influences a subsequent memory-based decision made about the same individual.

Effects of a Stimulus-Based Judgment on Subsequent Memory-Based Decisions

It is possible that the information that a person selectively samples from memory and considers when making a memory-based judgment will be similar in composition to the information available when an initial stimulus-based judgment is made, especially when both judgments occur close together in time. That is, in both cases a person may simply review the factual stimulus information (either as it is presented or from memory) and integrate it into a single response. Some amount of forgetting of the stimulus information might occur in the case of the memory-based judgment, but this would not represent an important difference in the composition of the

Portions of these experiments were reported at the annual meetings of the American Psychological Association in Chicago, September 1975, and in Washington, D.C., September 1976. The research was supported by National Science Foundation Grant GS-38604. For their help in analyzing the data and preparing the manuscript we thank David Ronis, Janet Dukerich, and Barbara Turpin.

sampled information as long as the forgetting was unselective.

Alternately, there are several ways in which an initial judgment might affect the cognitive representation a person forms about another individual as well as the information likely to be sampled from memory when a later memory-based decision is made. One way would be to make available from memory new thoughts or beliefs (apart from the items of stimulus information) that could be recalled and used as the basis of a decision. Such potentially available cognitions would include memory for the initial judgment as well as any person characteristics normally associated with that judgment. It has been shown, for example, that people are sometimes able to remember their own cognitive responses better than the stimulus information on which such responses are based (Greenwald, 1968). Furthermore, research exists demonstrating that people rely on abstracted inferences and affective impressions in addition to factual information in decision tasks (cf. Posner & Snyder, 1974). Thus, if a person were to decide upon meeting someone that the new acquaintance would probably be a good lawyer, she or he might later conclude that the same person would make a good judge, simply because, being a "good lawyer type," the acquaintance would likely be intelligent and judicious. Such a judgment process would be different from, and highly dependent on, the earlier stimulus-based judgment (i.e., this person would make a good lawyer).

A second way in which an initial judgment might alter the thoughts that are processed when a later memory-based judgment is made would be to influence the likelihood that different subsets of the original stimulus information would later be recalled. There are at least two reasons why, following an initial judgment, stimulus information relevant to that judgment should be remembered better than irrelevant information. First, it has been shown that the more deeply an item of information is processed when it is first encountered, the better it will later be remembered (Craik & Lockhart, 1972; Craik & Tulving, 1975). When a person makes an initial stimulus-based judgment about someone, it seems likely that she or he will pay greatest attention to, process more deeply, and remember better information that is relevant to making that judgment. Second, if an initial judgment is later remembered, it could easily serve as a cuing mechanism and facilitate the recall of information that had been instrumental in reaching the judgment (cf. Tulving & Thomson, 1973; Tulving & Watkins, 1975). Both processes, then, would likely result in judgment-relevant information being remembered better than judgment-irrelevant information when memory-based person judgments are made.

Availability Versus Retrieval Selectivity

In considering how an initial stimulus-based judgment influences a subsequent memory-based judgment, it is necessary to distinguish between the entire set of thoughts a person might have about another and the cognitions that are selectively sampled in the process of reaching a specific decision about that person. For example, research by Geva (1977), Lingle and Ostrom (in press), and Lingle, Geva, Ostrom, Leippe, and Baumgardner (in press) has provided evidence that an initial stimulus-based judgment influences how subjects cognitively represent a described person, as measured by memory for the stimulus traits and freely generated thoughts used to describe the stimulus person. However, such descriptions and recall measures do not identify how an initial judgment affects the set of cognitions that is sampled and actually used when a later memory-based judgment is made. To study this problem, the three experiments reported in this article used decision time as a basis for making inferences about the set of cognitions subjects rely on when they make memory-based person judgments. Experiment 1 was designed to determine whether decision time is affected by the degree of similarity between a first (stimulus-based) and second (memory-based) judgment. Experiments 2 and 3 used decision time to test three alternative processing models capable of accounting for the results of Experiment 1.

Experiment 1

If an initial stimulus-based judgment influences the manner in which a person cognitively represents another, thoughts that are recalled when a later memory-based decision is required should be more relevant to a similar subsequent judgment than to a dissimilar one. As a result, subjects should be able to make similar second judgments more quickly than dissimilar ones.

Experiment 1 tested the hypothesis that an initial judgment influences the set of cognitions on which a later judgment is based by determining whether the similarity between a first and second judgment influenced how quickly the second judgment could be made. If the first judgment has no systematic effect on the cognitive representation, then decision time for the second judgment should not be affected by the similarity between the two judgments. To test the hypothesis, a within-subjects design was used in which 12 subjects made two occupational judgments about 12 different stimulus persons. Subjects made each of their second judgments without being re-exposed to the stimulus traits presented when they made their first occupational judgment. For some of the trials, the initially judged occupation was similar to the second occupation, whereas on other trials, the initial occupation was dissimilar to the second.

Method

Subjects. Subjects in the experiment included eight male and four female undergraduate students from Ohio State University who participated in partial fulfillment of an introductory psychology course requirement. Subjects were randomly assigned to one of 12 different stimulus presentation orders used in counterbalancing the design.

Procedure. Upon arriving, each subject was seated in a desk chair beside a slide projector. A toggle switch was mounted on the arm of the chair that could be moved to the right (labeled "good") or to the left (labeled "bad"). Subjects were told that as part of a study on job counseling they would be asked to role play a job placement counselor and make a series of decisions concerning the suitability of hypothetical individuals for different occupations. It was explained that at the beginning of each trial, an initial occupation would be projected on the wall (approximately 2.5 m in front of the subject) followed by a slide containing four traits describing a stimulus person. The subject was to consider the suitability of the person for the job previously shown. After the traits had been displayed for a fixed period of time, the initial occupation was again presented, and the subject was asked to register his or her decision by moving the toggle switch to the good or bad position. The stimulus traits were displayed for a fixed 20 sec in order to minimize the possibility that subjects would rush through their judgments without considering all of the stimulus information. Pilot testing indicated that 20 sec was sufficient time for subjects to read the four traits, form an initial impression, and decide whether they thought the person would be successful in the designated occupation.

After a subject registered his or her initial occupational rating, a second occupation was shown, and the subject was asked to judge the suitability of the same stimulus person for this second profession. The subject was told to register the decision for this second judgment as soon as he or she was able to make it. Finally, a blank slide was presented to indicate the end of the trial. The process was repeated with a new set of traits and occupations until each subject had made a pair of occupational judgments for 12 different stimulus persons. On each trial, the blank slide and initial occupation were each displayed for 5 sec; the slide with four traits appeared for 20 sec. The two decision slides followed one another immediately, each being changed 3 sec after the subject had indicated his or her judgment. Two practice trials (one with a similar and one with a dissimilar pair of judgments) were repeated until both were completed without a mistake, in order to ensure that subjects understood the procedure. At the end of the experiment, probes for suspicion were conducted, and subjects were debriefed as to the purpose of the research.

Second decision time was measured from the moment at which the slide change mechanism of a Kodak Carousel 800H projector was activated, displaying the stimulus slide, to the point at which the subject moved the response switch. Decision time was measured by a Hewlett-Packard 12.5-MHz electronic counter and was automatically recorded.

Design and stimulus materials. Twelve groups of four occupations were generated. Each group contained two pairs of similar occupations, each of which was dissimilar from the occupations of the other pair (e.g., store clerk/salesman – lawyer/judge). Three independent judges demonstrated 100% agreement in judging each pair of similar occupations to be more similar than any possible dissimilar pair of occupations within the same occupational group (according to the criterion that "the occupations would require individuals with similar characteristics"). Each group of four occupations was paired with four randomly selected descriptive traits chosen from Anderson's (1968) trait-adjective list.

A completely within-subjects design was used in which each of the 12 subjects judged one pair of occupations from each of the 12 occupation groups.

The design was counterbalanced so that across the 12 subjects, each occupation appeared twice with each of the three occupations in its group, one time as the initial judgment and one time as the second judgment. Consequently, over the 12 subjects, each occupation within an occupational group was used as an initial judgment three times, as a second dissimilar judgment two times, and as a second similar judgment one time. The order of presentation of similar and dissimilar occupational pairs was counterbalanced across the 12 subjects by means of a Latin square (12 subjects being the minimum number of subjects that allowed complete counterbalancing of occupations across subjects).

Results and Discussion

During the debriefing, none of the subjects was able to verbalize any part of the experimental hypothesis, nor did any subject indicate an awareness that decision time was the principal dependent variable.

A test of the experimental hypothesis depended on an examination of subjects' second decision times. To review the alternative possibilities, if subjects unselectively review the stimulus information both when they make an initial stimulus-based judgment and when they make a subsequent memory-based judgment, the similarity of the first judgment to the second should not affect how quickly the later decision is made. On the other hand, to the extent that subjects base a second judgment on a set of remembered cognitions that is influenced by an initial judgment, they should make second similar judgments more quickly than second dissimilar judgments. Consistent with this latter alternative, mean decision time was significantly shorter for similar occupational judgments than for dissimilar judgments (Ms = 5.2 versus 6.3 sec, respectively), $t_{dep}(11) = 2.78$, $p < .02$. When examined individually, 10 out of the 12 subjects spent less time on the average in making similar as opposed to dissimilar second judgments. This was significant by the sign test ($p < .04$).

As might be expected, the subjects' second decisions matched their first decisions more often when they made similar (as opposed to dissimilar) second judgments (81% versus 63%, respectively). It was conceivable, therefore, that the differences in second judgment times resulted merely from subjects consistently making two matching responses more quickly than two nonmatching responses, not from the difference in relevance of their remembered impressions to their second judgments.

To examine this alternative explanation, the point-biserial correlation between second decision time and whether a second decision matched its corresponding first decision was computed for both the similar and dissimilar second judgment conditions. In the similar conditions, there was a small positive correlation ($r = .17$) such that subjects showed a slight tendency to make faster decisions when they made two matching judgments. However, in the dissimilar judgment conditions, the correlation was slightly negative ($r = -.15$). The correlation across both experimental conditions was $-.04$. Thus, the pattern of correlations did not support the explanation that the decision-time differences resulted from subjects persistently making matching second responses more quickly than nonmatching ones.

The difference in judgment times also did not appear to result from subjects making a disproportionate number of negative responses in either of the two conditions. The percentage of negative responses was almost identical (54% for similar versus 57% for dissimilar). Furthermore, the point-biserial correlation between second-decision valence and response time was negligible (the correlations for the dissimilar, similar, and combined conditions were .00, $-.03$, and .01, respectively).

Although the results from Experiment 1 are inconsistent with the thesis that subjects based their second judgments on an unselected review of the presented stimulus traits, they do not discriminate between any of the several alternative information-processing models capable of accounting for the differences in similar and dissimilar judgment times. Experiments 2 and 3 were designed for this purpose.

Experiment 2

In the introduction, three distinct categories of remembered cognitions on which a

subject might base a second judgment about a person were identified: (a) traits originally used to describe the person, (b) a previous judgment the subject had made about the person, and (c) characteristics associated with an earlier judgment. Several models of how these three types of cognitions are used singly, and in combination with each other, would be capable of accounting for the differences in judgment times obtained in Experiment 1. In this section, three such models are described. Each model makes a different prediction about how the pattern of second judgment times observed in Experiment 1 would be affected by the number of traits (set size) used to describe the stimulus person. Experiment 2 manipulated both similarity and set size in order to test which of the models best describes how subjects process information when they make second occupational judgments. As with any such test, the three models (and their differing predictions) rest on several assumptions that are briefly identified prior to our discussing the models themselves.

The first such assumption is that the amount of time subjects require to review a set of information items in memory increases as the number of items in the set increases. This assumption is empirically well supported and has been shown to hold true in a wide range of cognitive processing tasks including set inclusion tasks (Sternberg, 1969), person-trait identification tasks (Posner & Snyder, 1974), and paragraph comprehension tasks (Kintsch, 1974).

A second assumption is that the amount of time subjects require to make a judgmental response in this task, once they have reviewed the set of cognitions on which the occupational judgment will be based, is independent of the number of cognitions that are reviewed. While this assumption is less well supported empirically than the first, there is evidence that in at least some judgment tasks, response time is independent of the amount of information that is reviewed in memory to make the judgment (cf. Shanteau & McClelland, 1975).

A final assumption of Experiment 2 (and Experiment 3) is that the amount of time required to make a judgment is a direct function of the relevance of a subject's cognitive representation to the judgment. It is assumed that the less relevant a set of remembered cognitions is to a judgment, the more time a subject will have to spend in reviewing his or her cognitive representation in order either to find judgment-relevant cognitions or to generate judgment-relevant inferences.

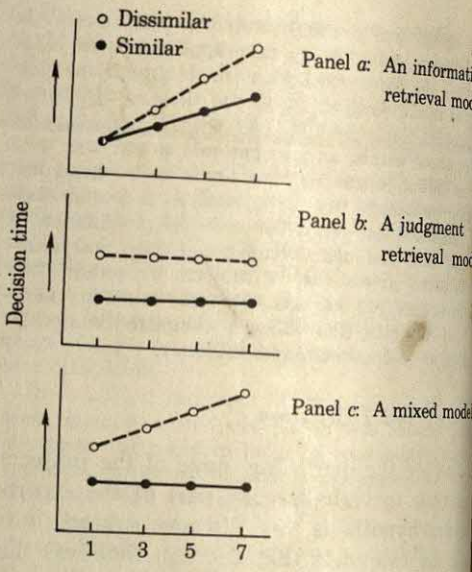

Figure 1. Predicted second judgment times for three different processing models when judgment similarity and set size are both varied.

With these assumptions as background, the three processing models tested in Experiment 2 can be described. The patterns of decision times predicted by each model when judgment similarity and trait set size are varied are displayed in Panels *a*, *b*, and *c* of Figure 1.

Three Models of Memory-Based Impression Judgments

An information-retrieval model. One model capable of accounting for the results of Experiment 1 posits that when subjects make their second occupational judgments, they serially review from memory the stimulus traits until they feel they have considered a sufficiently representative proportion of the available factual information to reach a decision. The major effect of the first judgment is to increase the probability that traits relevant

to the first decision will more readily be recalled to mind as compared with traits irrelevant to that decision. Since the amount of time required to review a set of items in memory is assumed to increase as set size increases, subjects in both the similar and dissimilar conditions should take longer to make their judgment as the amount of information in the person description increases. However, something else should also occur as set size increases. Since some percentage of the traits used to describe each stimulus person is relevant to the first judgment (e.g., 50%), the absolute number of relevant traits—and the time required to recall a representative number of these traits—will increase with set size. When subjects are making a similar second occupational judgment, these traits, being relevant to the second judgment as well, should be sufficient to make a decision. However, when making a dissimilar second judgment, subjects should not find these traits particularly helpful, since the dissimilar occupation was selected to require dissimilar abilities. In the dissimilar condition, then, subjects should have to recall the remaining traits in the set. Since the number of remaining traits will also increase with set size, subjects will have to spend additional time remembering and reviewing them. As a result, the average *difference* in decision time for similar and dissimilar second judgments should increase as set size increases. This pattern of results is depicted in Panel *a* of Figure 1.

A judgment-retrieval model. In the introduction, it was argued that an initial decision and its associated characteristics may serve as the basis for subsequent judgments. The second model focuses on retrieval of the initial judgment rather than on retrieval of the information or events on which the first impression was based. If subjects tend to base a second judgment on an initial judgment (and its associated characteristics), the number of cognitions considered in reaching a second decision should be independent of the number of stimulus traits initially used to describe a person. As a result, neither similar nor dissimilar judgment times would be expected to increase with set size. However, because the initial judgment and its related attributes would be less relevant to the second judgment in the dissimilar (as opposed to the similar) condition, subjects would be expected to spend additional time reaching a decision in the former situation. The pattern of decision times that would be expected is pictured in Panel *b* of Figure 1.

A mixed model. People are flexible information processors capable of using myriad decision strategies. It is possible that the difference in decision times in Experiment 1 came about because subjects used different decision strategies in making the two types of judgments. When subjects are faced with two very similar judgments, they may tend to base their second decision on their first, without considering the original stimulus information. However, when confronted by a dissimilar second judgment, subjects may find their first judgment insufficient grounds for the second and begin to review from memory the previously presented stimulus traits. In such a case, decision time for dissimilar judgments would increase with set size, whereas decision time for similar judgments would not. The pattern of response times would then be expected to parallel Panel *c* of Figure 1.

To test which of the three models best accounts for the similarity effect of Experiment 1, two sequential replications of Experiment 2 were conducted. In Replication 1 homogeneous trait sets, comprised of either all positive or all negative traits, were used to describe the stimulus persons. In Replication 2, heterogeneous trait sets, consisting of both positive and negative characteristics, were employed. The purpose of the two replications was to extend the generalizability of the results to more than one configuration of person information. Conceivably, the decision strategy adopted by a subject is affected by the degree of heterogeneity in the information set. For example, people may be more prone to engage in information retrieval than judgment retrieval with heterogeneous (as opposed to homogeneous) stimulus ensembles.

Both replications in this study used a within-subjects design in which subjects made pairs of occupational judgments about 12 different stimulus persons. As in Experiment

1, subjects made their second judgments without access to the stimulus traits. Half of these second judgments were similar to a first judgment and half dissimilar; an equal number of the 12 stimulus persons each subject evaluated were described by two, four, and six traits.

Method

Subjects. Subjects were 48 undergraduates from Ohio State University who participated in the experiment in partial fulfillment of an introductory psychology course requirement. In Replication 1, 11 male and 13 female subjects participated; in Replication 2, the subjects were 14 males and 10 females. As in Experiment 1, subjects were randomly assigned to one of the counterbalancing presentation orders.

Procedure. The experimental procedure and instructions to the subjects were identical to Experiment 1. Subjects were first shown an initial occupation, followed by a set of stimulus traits that was displayed for 20 sec. Thereafter, they were asked to register their decision concerning the described person's suitability for the initially displayed occupation, as well as for a second occupation that was either similar or dissimilar to the first. As in Experiment 1, subjects were given a fixed amount of time to study the traits and reach their initial occupational decision, in order to maximize the probability that they would take time to consider all of the stimulus traits.

In Experiment 2, the number of practice trials was increased to three in order to include stimulus persons described by each of the three set sizes (two, four, and six traits). Subjects made similar occupational judgments in one of the practice trials and dissimilar judgments in the other two.

Design and stimulus materials. Twelve groups of three occupations were selected from the occupations used in Experiment 1. Each of these triads consisted of one occupation arbitrarily selected to be used as a second occupational judgment and two to be used for the first judgment, one similar and one dissimilar to the second occupation.

In each replication, 24 subjects made two sequential judgments about 12 stimulus persons. The second judgment was preceded by a similar first occupational judgment for half of these stimulus persons and by a dissimilar first occupational judgment for the other half. Likewise, one third of the stimulus persons judged were described by two traits, one third by four traits, and one third by six traits, thus providing two within-subjects replications of the 2×3 design (Type of First Judgment $\times$ Set Size). All subjects judged the 12 second occupations in an identical order. Each subject was matched with another who saw identical sets of stimulus materials, except that if one subject judged the similar first occupation in a triad, the second subject judged the dissimilar occupation. These subject pairs then formed the unit of counterbalancing in the rest of the design.

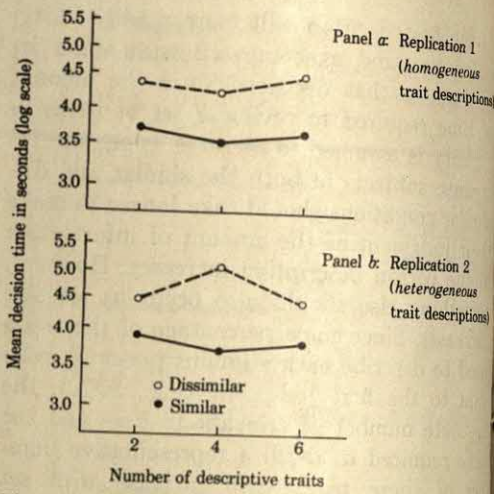

Figure 2. Mean second occupational judgment times from Experiment 2 as a function of judgment-pair similarity and set size.

For each of the two sequential replications, four lists of 12 traits were selected from Anderson's (1968) trait-adjective list. In Replication 1, two of the lists were selected from the positive half of the scale and two from the negative half of the scale, providing evaluatively homogeneous sets of traits. In Replication 2, traits for all four lists were selected from the middle three fifths of the scale, providing heterogeneous descriptions containing both positive and negative adjectives.

Counterbalancing of the traits across judgment similarity and set size for the 12 subject pairs in each replication was achieved by the method of cyclical replications. Traits within each list were randomly ordered from 1 to 12. The traits in each list were then sorted into the three experimental set sizes in 12 unique ways by simply moving the first trait to the end of the list and grouping the remaining traits in order into sets of two, four, and six. For example, (1, 2), (3, 4, 5, 6), and (7, 8, 9, 10, 11, 12) was the first group of sets; (2, 3), (4, 5, 6, 7), and (8, 9, 10, 11, 12, 1) was the second, and so forth. Three person descriptions were therefore obtained from each of the four lists to provide the 12 trait sets needed for each subject. The 144 stimulus persons generated in this manner were counterbalanced so that each trait appeared equally often for each level of set size and similarity. This counterbalancing scheme assured that none of the traits was presented to a subject more than, or less than, once.

Results and Discussion

Replication 1. As in Experiment 1, a test of the three models depended on a comparison

of subjects' second, memory-based judgment times. Natural log transformations of these response times were performed prior to the data analyses in order to eliminate a strong correlation between the cell means and variances (cf. Winer, 1971, p. 400). Analyses of subjects' untransformed judgment times were also conducted and produced results similar to the analyses of transformed scores. None of the statistical tests for either Experiment 2 or Experiment 3 that are appropriate for discriminating between the several models differed in significance as a function of whether the raw or transformed scores were used in the analysis. Subjects' retransformed mean decision-time scores for Replication 1 are presented in Panel *a* of Figure 2. The scores were analyzed using the multivariate analysis of variance approach for within-subjects designs as discussed by Poor (1973).[1]

The first replication involved homogeneous trait descriptions. The analysis of subjects' transformed second judgment times yielded a significant effect for similarity, $F(1, 23) = 14.7$, $p < .001$, replicating the principal finding of Experiment 1. However, no significant main effect or interaction for set size emerged (both Fs < 1).

Replication 2. Subjects' scores from Replication 2 (heterogeneous trait descriptions) were analyzed in an identical manner to the scores from Replication 1. The retransformed means are displayed in Panel *b* of Figure 2. The analysis again produced a significant main effect for the similarity of the second judgment, $F(1, 23) = 30.8$, $p < .001$, and a nonsignificant main effect for set size ($F < 1$). The interaction term approached significance, $F(2, 22) = 2.88$, $p < .10$. This borderline interaction was due entirely to the quadratic component of the set-size factor, $F(1, 23) = 6.02$, $p < .03$. The interaction term for the linear trend produced an F of less than 1.

While the results of both replications were most consistent with a judgment-retrieval model, two anomalies emerged in the pattern of results when heterogeneous, as opposed to homogeneous, trait sets were employed. First, in Replication 2 a quadratic interaction was obtained, raising the possibility that a more complicated version of the mixed model might be required to explain the manner in which subjects processed heterogeneous information sets. Second, subjects took slightly longer to make a second decision when heterogeneous, as opposed to homogeneous, trait sets were used to describe the stimulus person (Ms = 4.22 versus 3.99, respectively). A clear interpretation of the source of these differences was impossible, since the two replications were conducted during different months in the academic quarter, using different subject populations. A third experiment, to be reported below, was therefore conducted in which heterogeneity of the trait sets was manipulated as a separate within-subjects factor.

First judgments. As discussed earlier, the test of the three models involved the assumption that the time required to review items in memory increases as set size increases. In Experiment 2, subjects' first judgments were based on sets of differing sizes. However, the design of this (and the following) study precluded using first-decision times to verify this assumption. As previously described, in both studies subjects were first shown the occupation and then given a fixed amount of time to consider the traits, regardless of set size. Subjects were instructed to reach their judgment during the time the stimulus items were exposed and to report that decision when the traits were removed and the first decision reshown. Because there was no reason for subjects to review from memory the traits when reporting their first judgment, decision time for first judgments was not recorded.

Experiment 3

Experiment 3 was similar to Experiment 2 except for two changes. First, a wider range

[1] This approach analyzes within-subjects factors by defining a set of new variables that incorporates the elements of the within-subjects effects. An analysis of variance (sometimes univariate, sometimes multivariate) is then performed on the transformed variables. The principal advantage of the multivariate approach is that it is based on a less restrictive set of assumptions than the traditional within-subjects analysis. In the present report, boldfaced F values are multivariate values using Wilks's Lambda criterion.

of set sizes was used in order to insure that the findings of Experiment 2 were not the result of a restricted range. The set sizes used were one, three, five, and seven traits. The inclusion of a condition in which the stimulus person was described by a single trait also provided an additional test between the models. Because Experiment 3 was designed in such a way that no systematic difference existed in the relevance of the single trait descriptions to subjects' second judgments, the information-retrieval model (in which subjects rely solely on remembered stimulus traits) would not predict any difference in decision times for similar and dissimilar judgments. On the other hand, the judgment-retrieval model would predict a longer decision time for subjects' dissimilar second judgments even with only one trait, since a subject's first judgment would differ in relevance to his or her second in the two conditions (see Figure 1).

A second change incorporated into Experiment 3 was that the heterogeneity of the person descriptions was included as a separate within-subjects factor. This was done because of the unexpected quadratic interaction with heterogeneous sets in Experiment 2. In Experiment 3, each subject judged an equal number of stimulus persons who were described by a homogeneous trait set (either all positive or all negative) and a heterogeneous trait set (including both positive and negative traits).

Method

Subjects. Subjects included 11 male and 21 female undergraduates from Ohio State University who participated in partial fulfillment of a course requirement. These subjects were randomly assigned to the 32 stimulus presentation orders used to counterbalance the design.

Procedure. The experimental procedure and instructions to the subjects were similar to those used in Experiments 1 and 2. The only difference was that in this case, subjects were required to complete four practice trials, which included stimulus persons described by each of the four set sizes. For two of these practice trials, subjects judged pairs of similar occupations; for the other two, they judged dissimilar pairs.

Design and stimulus materials. The basic design and stimulus materials of Experiment 3 were similar to Experiment 2. However, because four set sizes were employed, the counterbalancing scheme required that 32 subjects (16 pairs) be used, each of whom made pairs of occupational judgments about 16 different stimulus persons. In order to include composition of trait sets as a within-subjects factor, 8 of the 16 stimulus persons judged by each subject were described by traits selected randomly from the complete range of Anderson's (1968) list, thus producing heterogeneous descriptions. Of the remaining eight descriptions seen by each subject, half were comprised of traits selected from the positive portion of Anderson's list and half from the negative portion, thus providing evaluatively homogeneous descriptions. As in Experiment 2, the counterbalancing of traits across similarity and set size was achieved by cyclical replications. In the case of Experiment 3, each list consisted of 16 traits so that set sizes of one, three, five and seven could be generated (i.e., $1 + 3 + 5 + 7 = 16$).

Results and Discussion

Effects of trait heterogeneity. One purpose of Experiment 3 was to determine if the differences in subjects' pattern of judgment times for heterogeneous and homogeneous trait sets observed in Experiment 2 were reliable. The first question investigated was whether the quadratic interaction between judgment similarity and set size was replicated for the heterogeneous trait sets. This was examined in several ways. First, the design of Experiment 3 permitted a statistical test of whether the trait-set composition (homogeneous versus heterogeneous) affected the shape of the Similarity × Set Size interaction. This test (the three-way interaction between judgment similarity, set size, and trait-set composition) proved to be nonsignificant, $F(3, 29) = 1.96$, $p < .20$. An additional analysis was performed on the heterogeneous data alone, and neither the overall interaction between similarity and set size, $F(3, 29) = 1.78$, $p < .20$, nor its quadratic component, $F(1, 31) = 1.02$, $p < .40$, was significant.

Finally, subjects' mean judgment times for heterogeneous trait sets were plotted and visually examined. This examination showed that there was no tendency for the similar and dissimilar judgment times to reconverge between Set Sizes 5 and 7 as they had reconverged between Set Sizes 4 and 6 in Experiment 2. In sum, there was no evidence that the quadratic interaction found in Ex-

periment 2 (Replication 2) was replicated in Experiment 3.

The second question examined was whether the tendency found in Experiment 2 for subjects to take longer with heterogeneous than with homogeneous trait sets was replicable. This was not the case. The main effect for trait-set heterogeneity on subjects' second judgment times was nonsignificant ($F < 1$).

Test of the three models. Because trait-set heterogeneity had no detectable effect on subjects' second judgment times, this factor is not discussed further. In order to test the three models, the data were analyzed in a similar manner to the data of Experiment 2. Subjects' retransformed response times, combined across trait-set replications, are presented in Figure 3. As in both Experiments 1 and 2, the judgment similarity main effect was significant, $F(1, 31) = 31.9$, $p < .001$. Neither the set-size effects nor the Set Size × Judgment Similarity interaction reached significance, $F(3, 29) = 2.27$, $p < .15$, and $F < 1$, respectively. Thus, even with an increased range of set sizes, the pattern of results obtained in Experiment 2 was replicated and best supported the judgment-retrieval model.

This model was further supported (and the information-retrieval model infirmed) by the fact that even when subjects made judgments on the basis of only one trait, 75% of them took longer on the average to make a second dissimilar judgment than a similar one (sign test, $p < .004$). It therefore would appear that even subjects in the single-trait condition were recalling cognitions that differed in relevance to their second occupational judgments.

Combining Experiments 2 and 3. Although no statistical statement can be made about the veracity of the null hypothesis regarding the absence of a set-size main effect or interaction with similarity, it is possible to aggregate the findings across experiments in a way that allows all the relevant available data to be brought to bear on a particular hypothesis. Winer (1971, p. 49) outlines a procedure whereby individual significance tests from a series of experiments may be combined to test a single hypothesis. If different samples

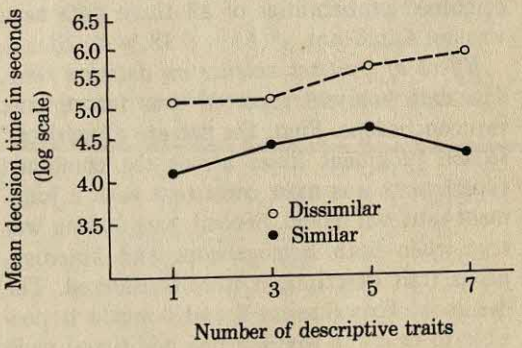

Figure 3. Mean second occupational judgment times from Experiment 3 as a function of judgment-pair similarity and set size.

are employed in each experiment, an overall probability statement can be computed by aggregating the natural logarithms of the independent probability values and comparing this aggregation with the chi-square distribution. In the present case, such a test can be made even more sensitive by considering just the linear component of the set-size effect, since it is the component that differentiates between the three models being considered.

The first test performed on the combined experimental data was a test of the linear interaction between judgment similarity and set size. Such an interaction is predicted by both the information-retrieval and mixed-judgment models, but not by the judgment-retrieval model. The F values of this linear interaction for all three data sets (cf. Figures 2 and 3) were less than 1, and the significance test based on the combined probabilities was also nonsignificant, $\chi^2(6) = 3.46$, $p < .50$.

The judgment-retrieval model predicts not only the absence of an interaction between judgment type and set size but also the absence of a linear increase in decision time across set size. A test of this hypothesis was conducted by collapsing across judgment type and analyzing the linear trend of decision times over set size. Whereas for both replications of Experiment 2 this analysis yielded Fs of less than 1, the corresponding analysis of Experiment 3 yielded a significant result, $F(1, 31) = 6.25$, $p < .02$. However, a test of the hypothesis that subjects' judgment times increased with set size, based on the

combined probabilities of all three data sets, was not significant, $\chi^2(6) = 9.38$, $p < .20$.

Effect of trait-set valence on decision time. The data analyses reported thus far support two conclusions. First, the pattern of subjects' second judgment times across the combined experiments was most consistent with a judgment-retrieval model. Second, this finding was true when both homogeneous and heterogeneous trait descriptions were considered. The design of Experiments 2 and 3 made it possible to examine whether one additional variable, trait-description valence, might limit the generalizability of the experimental results. This was possible because in both Experiments 2 and 3, to avoid a valence expectancy set, half of the homogeneous trait descriptions were constructed of positive traits and half were constructed of negative traits.

Two separate analyses indicated that the absence of an interaction between judgment similarity and set size held for both positive and negative trait sets. First, the three-way interaction between trait-set valence and the other two variables was not significant: The analysis of the linear component of the three-way interaction, based on the combined probabilities from Experiments 2 and 3, yielded a value of $\chi^2(4) = 7.81$, $p < .10$. Second, the two-way interactions between judgment similarity and the set-size linear components were nonsignificant when subjects' judgment times for positive and negative trait sets were analyzed independently: The analyses of this interaction, based on the combined probabilities from the two experiments, yielded values of $\chi^2(4) = 4.72$, $p < .50$, for the positive trait sets, and $\chi^2(4) = 4.68$, $p < .50$, for the negative trait sets.

The strength of the similarity effect also was not significantly affected by trait valence. For both types of traits, subjects took longer to make second dissimilar, as opposed to similar, judgments. This result was indicated by the absence of a significant interaction between trait valence and judgment similarity; the analysis based on the appropriate combined probabilities yielded a value of $\chi^2(4) = 2.19$, $p < .50$.

Finally, the question of whether trait valence in any way modified the finding that decision time is independent of set size was tested by analyzing the linear interaction between trait-set valence and set size. In contrast to the other analyses, the linear interaction between trait-set valence and set size was significant for both Experiments 2 and 3, $F(1, 11) = 8.20$, $p < .02$, and $F(1, 15) = 7.56$, $p < .02$, respectively,[2] as well as significant for the combined analysis, $\chi^2(4) = 16.80$, $p < .005$.

To determine the nature of this interaction, separate analyses of the linear trends of judgment times across set size for the positive and negative trait sets were conducted. These analyses indicated that when subjects considered negative trait sets, the linear component of their second judgment times did not vary significantly across set size, $F(1, 11) = 1.14$, $p < .31$, for Experiment 2; $F(1, 15) = 1.38$, $p < .26$, for Experiment 3; $\chi^2(4) = 5.06$, $p < .25$, for the combined probabilities. On the other hand, when subjects considered trait sets that consisted solely of positive traits, there was a significant linear increase in their second judgment times as the number of traits used to describe the stimulus person increased, $F(1, 11) = 4.99$, $p < .05$, for Experiment 2; $F(1, 15) = 10.87$, $p < .005$, for Experiment 3; $\chi^2(4) = 16.70$, $p < .005$, for the combined probabilities. This effect is shown in Table 1, where subjects' retransformed mean decision times for positive and negative trait sets from Experiments 2 and 3 are displayed. As can be seen, there was a tendency for subjects' judgment times to decrease as set size increased for negative trait sets. This tendency approached in magnitude the increase in judgment time over set size for positive traits. The linear trend was sig-

---

[2] For design efficiency, both Experiments 2 and 3 contained a confounding between trait-set valence and judgment similarity. However, this confounding did not exist if pairs of subjects were considered as the unit of analysis and the three factors (judgment similarity, trait valence, and set size) were considered as within-(pairs of) subjects factors. It is for this reason that the degrees of freedom for the present analyses are halved. Such an analysis is possible using a multivariate approach, since variance-covariance homogeneity is not a required assumption (see Poor, 1973, p. 206).

Table 1
Mean Second Occupational Judgment Times as a Function of Trait-Set Valence and Set Size: Experiments 2 and 3

Valence	No. of descriptive traits		
	Experiment 2		
	2	4	6
Positive	3.87	4.11	4.42
Negative	4.28	3.64	3.77
	Experiment 3		
	1	3	5	7
Positive	4.28	4.39	5.32	5.09
Negative	5.33	4.94	4.65	4.58

Note. Response times are subjects' mean log scores transformed into seconds. For Experiment 2, each mean is computed from 48 responses (24 subjects providing two responses each); for Experiment 3, each mean represents 32 responses (32 subjects providing one response each).

nificant for positive but not for negative traits because the mean square error of the linear trend analysis for negative traits was more than three times as large as the mean square error for positive traits in both experiments. This implies substantially greater individual differences in the effect of set size for negative information than for positive information.

The finding that subjects' second judgment times increased more with set size when they considered homogeneously positive (compared with negative) trait sets would not be predicted by any of the three processing models. One possible explanation of this unexpected finding is that subjects, in addition to recalling their initial judgment, spent some time searching their memory for stimulus information that might disqualify a person from being successful at the occupation. For negative homogeneous sets, the ease (or speed) with which a subject could recall a sufficient number of relevant negative information items to disqualify a person from being successful in a particular occupation could be expected to increase as set size increased. However, when considering sets of homogeneously positive traits, as set size increased, subjects would have to search an increasing number of information items before proportionally sampling the stimulus items for possible disqualifying attributes.

If such a memory search strategy did account for the obtained interaction between negative and positive information sets and set size, it would appear that it supplemented (rather than replaced) a judgment-retrieval process. The absence of an interaction between trait valence and judgment similarity (along with the absence of a three-way interaction between these two factors and set size) indicates that subjects consistently took longer to make dissimilar, as compared with similar, second judgments when the stimulus persons were described by both positive and negative trait sets.

Availability of stimulus information in memory. The primary concern of all three studies was to uncover the kinds of information people selectively review in memory prior to making a person judgment. As noted in the introduction, this concern is distinct from assessing the kinds of stimulus information that can potentially be remembered by a person. Although the data of Experiments 2 and 3 suggest that people do not actively recall more stimulus items as a function of set size while making a judgment (at least not for homogeneously negative or heterogeneous stimulus sets), this should not be taken to mean that people are incapable of remembering more stimulus items when a person description contains more items of information. In Experiment 3, after subjects had made

their last occupational judgment, they were unexpectedly asked to list as many of the traits describing the final stimulus person as they could remember. Subjects were able to recall an increasing number of traits as the number of traits in the stimulus set increased. The mean number of accurately recalled traits, when subjects had seen descriptions containing one, three, five, or seven traits was 1.0, 2.6, 2.9, and 3.2, respectively, $F(3, 12) = 3.34$, $p < .06$. Thus, subjects were capable of recalling more traits as set size increased, even though there was little evidence that they were doing so while making their judgments.[3] Although the information-retrieval model did not adequately account for the pattern of response times found in the present decision setting, this model may well be appropriate in other contexts. The recall data show that people can, if required, recall more information items as set size increases in this type of sequential judgment task.

General Discussion

Summary and Conclusions

The research reported in this article was undertaken to investigate the selective retrieval process subjects employ when making memory-based judgments. The first study found that an initial stimulus-based judgment made about a person influenced how quickly subjects made a subsequent memory-based judgment about the same individual. The fact that a similar second decision was made more quickly than a dissimilar second decision indicated that subjects' memory-based judgments were not based solely on an unselective review of the stimulus information they had received.

Experiments 2 and 3 compared three different decision models that could account for the judgment similarity effect discovered in Experiment 1. Two stimulus-information-retrieval models were described that accounted for the similarity effect by postulating that selective sampling of the stimulus traits occurred when subjects made their second judgment. Neither of these models provided an adequate account of the decision-time differences. In fact, the most striking outcome of Experiments 2 and 3 was how impervious the similarity effect was to manipulations of the stimulus information. The magnitude of the similarity effect was undiminished by trait-set composition (heterogeneous versus homogeneous), trait-set valence (positive versus negative), and set size (one through seven items of person information). Even when subjects demonstrated 100% recall ability (as in Experiment 3, where only one stimulus trait was presented), 75% of them took longer to reach a second dissimilar (as opposed to similar) decision. The persistence and stability of the similarity effect proved most consistent with a judgment-retrieval model, which postulates that subjects base their second decisions on memory for their initial judgment and its associated characteristics.

Although stimulus-information-retrieval processes were not responsible for the judgment similarity effect, it cannot be concluded that such processes were totally absent in the present judgment task. There was evidence that subjects' judgment processes included a selective search for negative stimulus information in addition to recall of their initial judgment. When subjects were presented with a homogeneously positive set of descriptive traits, their mean judgment times increased as set size increased. However, when only negative traits were presented, there was a nonsignificant tendency for decision time to decrease as set size increased.

While subjects in the present decision task appeared to rely on their first impression judgments in combination with a memory search for disqualifying attributes, there is little doubt that their cognitive processing strategy for making memory-based decisions would be different in other settings. For example, had there been a substantial period of time be-

---

[3] The only other significant result from the analysis of the memory data was a significant effect for judgment type, $F(1, 12) = 4.84$, $p < .05$. Subjects in the dissimilar judgment condition recalled on the average more traits than subjects from the similar condition (Ms = 2.73 versus 2.08, respectively). However, this effect must be regarded with caution, since no such difference was found in a comparable person-impression sequential judgment task (cf. Lingle & Ostrom, in press).

tween the first impression judgment and the memory-based judgment, it would be much less likely that subjects could have remembered any specific item of descriptive information. Under such circumstances, they might have resorted solely to a judgment-retrieval process. Alternatively, a person might depend much more heavily on an information-retrieval process if there were sufficient incentive. This might be the case, for example, if the subjects were rewarded for a correct decision, were required to justify their second judgment, or perceived that the experimenter's hypothesis concerned memory for the traits.

Methodological Note

To understand the way in which people draw on memory when they make impression judgments, social psychologists will need to develop and adopt methodologies appropriate for investigating cognitive information processing. A number of investigators (cf. Anderson, 1977; Anderson & Hastie, 1974) have shown how decision time may be used to infer the structure of people's cognitive representations of others. The present studies demonstrate the way in which decision time may also be used to make inferences about how people draw on their memory in a person judgment task.

Although decision time represents a powerful, relatively unobtrusive measure of cognitive processing, there are problems associated with its use. Decision-time data are difficult to interpret without precise processing models that make clear alternative predictions. Such models invariably rest on multiple assumptions whose number tends to increase as the complexity of the decision being studied increases. Consequently, decision time is much more suitable for eliminating processing models than it is for providing definitive evidence that any single model is a true representation of the way in which people process information. Thus, the present studies provide relatively strong evidence that neither the information-retrieval model nor the mixed model, as described in this article, accurately reflects subjects' judgment process in this task. Other versions of these models, however, might account for the data better. For example, it may have been that in the present judgment context, subjects felt time-limited, as opposed to relevance-limited, in their memory search. That is, the lack of relationship between set size and decision time may have resulted from subjects tending to sample cognitions from memory for a fixed period of time rather than sampling a proportional number of cognitions. Although the interaction between trait valence and set size suggests that subjects were not tightly time-bound in their processing strategy, the possibility of this type of limitation cannot be ruled out. Consequently, the present support for judgment-retrieval processes must be regarded as tentative.

The existence of alternative explanations for the present findings reflects the fact that model building is an iterative process in which some models are eliminated while others are expanded and refined to conform with empirical regularities that have emerged from previous testing. We hope that the present studies represent only a first step in an evolutionary process that will result in the development of more complete models of the ways in which people selectively draw on memory when they make memory-based impression judgments.

Notice on Author Alterations

Effective January 1979, the procedure for billing authors for alterations will change. Authors of articles in APA journals are customarily charged for alterations on proofs that result from (a) authors' errors or omissions in the manuscript and (b) changes that result from authors' failure to review the edited manuscript or the proof. Until now, alteration charges have been determined by the number of lines affected by changes requested and have been based on 1974 printing rates. Beginning with the proofs for the first issues of 1979, authors' alterations will be determined not only by the number of lines affected but also by the number of figures and pages affected and will be based on current printers' rates.

This change in alteration billing is being made so that alteration charges will more closely reflect the actual cost of changes requested and may mean larger alteration bills for some authors. Authors are reminded that alteration charges apply only when changes are made on proofs and that *there is no charge* for changes made at the manuscript stage.

Personality Correlates of Susceptibility to Biasing Information

Elisha Y. Babad
School of Education
Hebrew University of Jerusalem
Jerusalem, Israel

Subjects were asked to score two drawings, one allegedly made by a high-status child and the other by a disadvantaged child. The difference between the scores that each subject attributed to the two drawings (compared to the objective base level) was the subject's bias score. High-bias subjects (with bias scores one standard deviation or more above the overall mean bias) described themselves as more reasonable than no-bias subjects (bias scores of zero), and as less emotionally extreme in the directions of toughness, tenderness, and level of enthusiasm. This pattern was interpreted as reflecting the need system suggestive of the dogmatic personality. In a second study, no differences were found between the extreme-bias groups in responses to self-report questionnaires and the Embedded Figures Test, and in political views. However, high-bias subjects responded *more extremely* than no-bias subjects to direct questions pertaining to their political ideology, independent of its content and direction, in line with the conception of dogmatism as a style of thinking independent of ideological content.

Experimenter bias effects, expectancy effects, and self-fulfilling prophecies of various types have been repeatedly demonstrated in a variety of populations, settings, content areas, and types of experiments (Rosenthal, 1966, 1969, 1971). In such studies, changes in dependent variables (mostly task performances) are attributed to the influence of biasing information, which is presumably task irrelevant. However, expectancy effects are *not* universally demonstrated in every study and every replication, and even when the overall effects are statistically significant, there are great variations in susceptibility to biasing information (Rosenthal & Rubin, in press).

I wish to thank my friends Daniel J. Davis for his helpful support, Bruce T. Oppenheimer for his continued participation and suggestions, and Chaim Schlezinger for his patient assistance in data analysis.

Requests for reprints should be sent to Elisha Y. Babad, School of Education, Hebrew University of Jerusalem, Jerusalem, Israel.

Variations in the influence of biasing information are probably caused by various factors, including design and procedure differences, nuances of delivery, and personality differences among subjects. This study focused on the latter factor, and an attempt was made to identify systematic personality correlates of susceptibility to biasing information.

McFall and Schenkein (1970) divided their subjects into extreme groups on several variables (need for achievement, field dependence). Then they divided each extreme group into two experimental groups and administered Rosenthal's (1966) photo-rating task to these groups, feeding one experimental group with "positive" expectancy and the other with "negative" expectancy. Laszlo and Rosenthal (1970) used a similar design, with dogmatism scores as the criterion for dividing the groups.

In a different design, each subject receives both positive and negative expectancy information, and the resulting difference between the subject's two performances serves as an

Copyright 1979 by the American Psychological Association, Inc. 0022-3514/79/3702-0195$00.75

index of susceptibility to bias. This design seems to be more powerful than the McFall and Schenkein design, since *each subject's* influenceability can be directly assessed. On the other hand, the disadvantage of this design is that the credibility of the cover story and of the biasing information (enough of a problem even when subjects receive only one type of biasing information) may be seriously hampered, limiting the range of experimental possibilities. Laszlo and Rosenthal (1970) used the first design and later created a measure of individual influenceability by computing the difference between each subject's mean photo rating and the mean photo rating obtained by the same experimenter from all his subjects contacted under the opposite condition of expectancy. The experimental situation chosen for the present study—test scoring—makes it possible to provide each subject with positive *and* negative expectancy information without losing credibility. In this design, subjects are asked to score mental tests of two "examinees," one allegedly of high status and the other of low status.

This type of study measures *suggestibility*, namely, the influence of the information on the performance of the receiver. Another possible type of study measures *communicability*, that is, the extent to which the receiver of the biased information influences the behavior of other people (Finn, 1972). Bias in scoring (e.g., Babad, Mann, & Mar-Hayim, 1975) exemplifies suggestibility effects, whereas teacher expectancy effects (Rosenthal & Jacobson, 1968) and photo-rating bias (Rosenthal, 1966) are examples of communicability effects. Suggestibility is a necessary, but not sufficient, component for communicability effects. It is interesting to note that McFall and Schenkein (1970) used *tape recordings* of experimenters in Rosenthal's photo-rating task, thus turning a communicability study into a suggestibility study.

In the present project, the Goodenough–Harris Draw-A-Person (DAP) Test (Harris, 1963) was used to determine subjects' susceptibility to biasing information. The advantages of the DAP test are its simplicity, the minimal experience it requires, and the short time it takes to learn the scoring system. While the first study in this report was exploratory, the second study was designed to test hypotheses formulated on the basis of the results of the first study.

Study 1

Method

Overview of the Study

Introductory psychology students were taught the scoring procedures of the Draw-A-Person Test and were then asked to score two drawings. The drawings were actually duplicated from the test manual, but the students were provided with falsified information alleging that one drawing was made by a disadvantaged, low-class child and the other, by a high-status, advantaged child. Later, the students completed a self-report personality inventory.

Subjects

Subjects were 133 students in introductory psychology classes at the School of Education of the Hebrew University of Jerusalem. All subjects were freshmen.

Procedure

The experiment was conducted in one (2-hour) session, the purpose of which (the students were told) was "to familiarize you with simple instruments of psychological evaluation via direct, first-hand experience." The instructor presented the Draw-A-Person Test and distributed a sheet summarizing the 73 scoring categories. The procedures for scoring were then taught, and the subjects practiced (a) by scoring a drawing on the board and (b) by scoring their neighbors' drawings. A practice sheet was then distributed, and the students were told that a reliability study would be conducted. The sheet was divided into two columns, each presenting a drawing of a man and information about the "child" who allegedly drew that picture. The information consisted of name, address, school, number of siblings, and parents' occupations and education. One child was described as coming from a high-status background (with a European name, Rubinstein), whereas the other child was depicted as a disadvantaged child of Moroccan origin (named Amsalem).

The drawings were actually duplicated from the DAP manual, so that their objective manual scores were initially known. To increase the credibility of the cover story, the drawing selected for the high-status child (Harris, 1963, p. 268, Figure 64) had a somewhat higher manual score than the drawing attributed to the low-status child (Harris, 1963, p. 271, Figure 72). Therefore, a difference of 3 points in favor of the high-status child represented "no bias."

(To double check, we asked at a later time five graduate students to score these drawings without adding the expectancy information. Their scores confirmed the 3-point difference between the two drawings.)

The instructor explained to the students that these drawings were photocopied from records collected in a recent study conducted in various Jerusalem schools. The instructor commented that "one can immediately see the difference between the drawings of Rubinstein and Amsalem" and proceeded to urge the students to be objective in their scoring, reminding them that the reliability of their scoring would be examined.

After the completion of the scoring, the Adjective Check List (ACL; Gough & Heilbrun, 1965) was distributed. The ACL consists of 300 adjectives, and subjects are asked to check those adjectives that describe them as they are (i.e., "actual-self" image). The ACL was chosen because of its nonpathological focus, the short time it takes to administer, and the availability of a Hebrew version.

Results

Overall Bias

The mean bias score (i.e., the difference between the scores of the drawings attributed to Rubinstein and Amsalem) of the 133 students was 6.47, the standard deviation was 5.9, and the bias scores ranged from −6 to 26 points. Considering a difference of 3 points as "zero bias," the t test yielded a highly significant result ($t = 6.77$, $p < .001$) This finding is another demonstration of bias in scoring (see Babad et al., 1975); for the purpose of this analysis of susceptibility to biasing information as a personality dimension, the wide range of individual differences in the bias scores is quite satisfactory.

Correlational Analysis and Construction of Personality Scales

The analysis of the ACL responses presented a problem. Gough and Heilbrun (1965) developed over two dozen scales for scoring the ACL, but these scales had never been standardized or empirically validated on Israeli subjects. Since numerous adjectives had changed considerably in the process of translation, it was inappropriate to use the American scales on the Israeli subjects. Some adjectives have a very special meaning or double meaning in American English (e.g., "queer"), other adjectives cannot be adequately translated for lack of an appropriate word in Hebrew (e.g., "zany"), and cultural nuances are not readily reproducible in Hebrew.

Being unable to use Gough and Heilbrun's scales (and lacking an alternative nonpathologically oriented test in Hebrew), we were compelled to construct new scales from the available data. Factor analysis and other multivariate methods were ruled out because of the small number of subjects (133) relative to the number of variables (300). The most viable alternative was to use the subjects' bias scores as reference and to construct ad hoc scales according to the correlations of the ACL adjectives with that score. By chance alone, 15 of the 300 correlations between the ACL adjectives and the bias score should have reached the .05 level of significance, and 30 correlations should have reached the .10 level of significance. The results showed 34 correlations significant at the .05 level and 57 at the .10 level, both of which exceed chance level.

Of the 34 correlations reaching the .05 level of significance, 28 (or 82%) were negative, indicating that the high-bias subjects tended to check these adjectives *less* frequently than the low-bias subjects. To further examine this finding, we computed the correlations between the bias score and (a) the total number of adjectives checked, (b) the number of favorable adjectives checked, and (c) the number of unfavorable adjectives checked. (This analysis seemed more legitimate than the use of Gough and Heilbrun's (1965) specific scales, since it dealt with *overall* numbers of adjectives.) Only the last correlation was statistically significant ($r = -.17$, $p < .05$), indicating that the more biased subjects tended to check unfavorable adjectives *less* frequently in describing themselves. Gough and Heilbrun (1965) state that the low-scoring person on the number of unfavorable adjectives "is more placid, more obliging, more mannerly, more tactful, and probably less intelligent" (p. 6).

Four distinct clusters emerged in the scrutiny of the adjectives significantly related

Table 1
Mean Scores of High-Bias and No-Bias Groups on the Four Ad Hoc Scales (Study 1)

Group	Scale			
	Reasonableness (13 items)	Over-toughness (38 items)	Over-tenderness (31 items)	Over-enthusiasm (20 items)
High bias (n = 25)	6.28	4.68	5.12	3.72
No bias (n = 34)	4.97	7.29	6.74	5.59
t test	1.87*	2.25*	1.80*	2.18*

* $p < .05$.

to the bias score. About two thirds of the "significant" adjectives fitted in these clusters, whereas no meaningful pattern could be detected connecting the remaining adjectives. On the basis of these clusters, four ad hoc scales were defined: (a) *Reasonableness.* In this cluster, subjects described themselves as very reasonable, adhering to values of sobriety and realism. Typical adjectives are *rational, reasonable, civilized, mature, relaxed,* and *discreet.* (The adjectives in this cluster were *positively* related to bias.) (b) *Over-toughness.* This factor emphasizes extremely forceful and egocentric interaction with, and control of, other people. Typical adjectives are *aggressive, autocratic, cruel, rude, dominant, hardheaded,* and *hostile.* (The adjectives in this cluster—as well as in the next two clusters—were *negatively* related to bias.) (c) *Over-tenderness.* This factor also consists of a rather extreme description, but the emphasis is on lack of forcefulness, dependence on other people, and an overly "soft" position. Typical adjectives are *softhearted, timid, defensive, dependent,* and *sensitive.* (d) *Over-enthusiasm.* This factor relates to a behavioral style of a particular nature, characterized by excess energy and activity. Typical adjectives are *enthusiastic, blustery, praising, energetic, spunky,* and *uninhibited.*

The definitions of these four factors and the 300 ACL adjectives were submitted to three experienced psychologists, who were asked to mark all adjectives fitting these definitions. The three psychologists were unaware of the correlations between the adjectives and the bias score. All adjectives appearing in the lists of all three judges were included in the new ad hoc scales. The four new scales consisted altogether of 102 (out of 300) ACL adjectives, the majority of which (66) had *not* been significantly related to the bias score; only 23 were significant at the .05 level.

Extreme Group Comparison

To examine the relationships between the ad hoc scales and the bias score, an extreme-group design was chosen, comparing high-bias to no-bias subjects. All subjects whose bias scores were one standard deviation or more above the overall mean of the bias scores were included in the high-bias group (n = 25). All subjects whose bias scores were at the "zero bias" plus or minus one (i.e., granting Rubinstein between 2 and 4 points more than Amsalem) were included in the no-bias group (n = 34). Scores on the four ad hoc scales were computed for the subjects in these extreme groups, and t tests between the scores of the high-bias and no-bias groups were calculated. All t tests yielded statistically significant ($p < .05$) differences; the pattern of these results is presented in Table 1. The high-bias subjects described themselves as more reasonable than the no-bias subjects, while the latter group was higher on all three "over" scales—over-toughness, over-tenderness, and over-enthusiasm.

Discussion

This pattern is extremely interesting. The subjects who showed more susceptibility to biasing information, and whose scoring of the

drawings was less objective, chose to describe themselves as more reasonable, rational, and objective and as less emotionally extreme. On the other hand, the subjects whose scoring was more objective and unaffected by the biasing information described themselves as less reasonable and as more extreme in several emotional directions. To interpret these results, it seems quite clearly indicated that the self-descriptions should *not* be viewed as reflecting real, "actual-self" attributes but as expressions of a need system and an "ideal-self" image. Thus, the high-bias person *needs* to see himself or herself as more reasonable and must *deny* the existence of any emotional extreme in his or her personality. The no-bias subjects are not necessarily less reasonable, tougher, or more tender than the high bias subjects, but they can more readily admit the existence of these extremes in their personality and do not need to hold on so strongly to the rational facade.

This image of the high-bias person seems familiar from the literature on authoritarianism and dogmatism: rigid adherence to and overemphasis of conventional values (being OK and reasonable); rejection of emotional extremes and of self-awareness that may threaten one's adjustment; and narrow range of consciousness. Extreme strength or weakness must be rejected as "not me" if one's attempt to be over-reasonable is to succeed.

In conclusion, the only personality correlate of susceptibility to biasing information inferred from the results of Study 1 is dogmatism. This is in line with the findings reported by McFall and Schenkein (1970) and by Laszlo and Rosenthal (1970). Moreover, the absence of findings on other personality correlates of susceptibility to bias in this study is also consonant with other reports (Laszlo & Rosenthal, 1970; Rosenthal, 1966).

Although it appeals to common sense that susceptibility to bias is a reflection of dogmatism, this conclusion in the present context is speculative and highly tentative. Consequently, Study 2 was designed to focus directly on various manifestations of dogmatism and their relations to susceptibility to biasing information. The instruments used in Study 2 to assess dogmatism included specific self-report questionnaires, a performance task of field dependence, and questions concerning political ideology.

Study 2

Method

Overview of the Study

Bias in scoring was measured in Study 2 as in Study 1. Immediately thereafter, the Embedded Figures Test (Oltman, Raskin, Witkin, & Karp, 1971) was administered to measure field dependence, followed by a self-report questionnaire with scales measuring dogmatism, locus of control, defensiveness, and impulsiveness. A week later, the subjects responded to several direct questions concerning their political views.

Subjects

A new sample was selected for Study 2, consisting of 179 introductory psychology students at the School of Education of the Hebrew University of Jerusalem. All subjects were freshmen, and the study was conducted at the beginning of the school year.

Procedure

The DAP experiment was conducted in replication of Study 1. The only exception was that the drawing attributed to the low-status child (Amsalem) was replaced by another drawing duplicated from the DAP manual. The new drawing (Harris, 1963, Figure 57, p. 264) had a *higher* manual score than the drawing attributed to the high-status child, but in superficial examination it seemed to be of poorer quality than the other drawing. This change was due to the investigator's eagerness to maximize the bias effect and increase the spread of the bias scores. In retrospect, it seems that a simple counterbalancing of stimuli would have been much more appropriate, and this change is regrettable. Contrary to the manual scores, the five judges who scored the two drawings without the expectancy information and without access to the scoring of these drawings in the DAP manual awarded the new drawing 5 points *less* than Rubinstein's drawing. Thus, the investigator's overeagerness resulted in a "boomerang effect." The manual scores were therefore discarded, and a difference of 5 points in favor of the high-status child was defined as "zero bias."

Immediately following the scoring of the two drawings, a short (16-item) version of the Embedded Figures Test (Oltman et al., 1971) was administered, with a time limit of 4 min. The students then filled out a self-report questionnaire containing the short version of Rokeach's Dogmatism Scale (Schulze, 1973); a locus of control questionnaire (Rotter,

1966); a defensiveness questionnaire (from Babad, 1974); the Impulsiveness Scale (Barratt, 1965); and several filler items.

In the next class session, the students were asked to provide ratings (on 5-point scales) to the following questions: (a) What is your political ideology?—from 1 (left) to 5 (right); (b) What is the *intensity* of your political views?—from 1 (very low) to 5 (very high); and (c) What is your position regarding "greater Israel"? (i.e., a dovish or a hawkish position concerning the possibility of returning territories on the West Bank of the Jordan River to the Arabs—from 1 (against—dovish stand) to 5 (for—hawkish stand).

Results and Discussion

Overall Bias

The mean bias score of the 179 subjects was 6.20, the standard deviation was 5.33, and the bias scores ranged from −5 to 23 points. Considering a difference of 5 points as "zero bias" (in accordance with the stricter scoring of the five judges and disregarding the manual scores), the t test yielded a significant result ($t = 3.00$, $p < .05$). This finding is yet another demonstration of bias in scoring. In addition, it constitutes a replication of the DAP method of affecting expectancy bias.

Extreme Group Comparison

As in Study 1, the analysis of personality correlates was carried out using an extreme-group design, and the same principles were employed to define the high-bias and no-bias groups. All subjects whose bias scores were one standard deviation or more above the overall mean of the bias scores were included in the high-bias group ($n = 20$), while all subjects whose bias score was 5 ("zero bias") constituted the no-bias group ($n = 18$).

The self-report questionnaires were analyzed in several ways. The responses of all 179 subjects to each of the scales (dogmatism, locus of control, defensiveness, and impulsiveness) were factor analyzed, and new factor scores were computed. *None* of the t tests (of total scales *and* of new factor scores) yielded a significant difference between the high-bias and no-bias groups. Thus, no correlates of susceptibility to biasing information were identified in these self-report questionnaires.

No significant difference was found between the scores of the high-bias and no-bias groups on the Embedded Figures Test. This finding is contrary to McFall and Schenkein's (1970) report, where a significant expectancy effect on Rosenthal's (1966) photo-rating task was found for groups of subjects defined as field-dependent according to their Embedded Figures Test performance.

Considering the three direct political questions (political ideology, intensity of political views, and position about returning territories to the Arabs),[1] no significant differences were found between the high-bias and no-bias groups, although a slight (insignificant) tendency of the high-bias subjects towards the right-wing and hawkish positions was detected. Following Rokeach's (1960) argument concerning "the authoritarian of the left," the subjects' responses to these questions were rescored according to their *level of extremity*, disregarding the direction of their content. Thus, ratings of 1 and 5 were scored as extreme (1), and 2 and 4 were scored as moderate (2), and a rating of 3 was scored as neutral (3). *The* t *tests of the extremity scores yielded a statistically significant* ($p < .05$) *difference, the high-bias subjects consistently taking a more extreme position in reacting to all three questions.* Thus, while the groups did not differ in the content direction of their political views, the high-bias subjects differed from the no-bias subjects in that they consistently responded more extremely to these questions.

In light of this finding, the responses to all self-report questionnaires were rescored according to their level of extremity, and the data were reanalyzed. No additional differences were found. Thus, the difference between the bias groups in the extremity of responding was limited to the direct political questions.

General Discussion

The findings of the two studies can be summarized as follows: (a) Bias in scoring was demonstrated and replicated. (b) High-bias subjects described themselves as more

[1] This study was conducted *prior* to President Sadat's peace initiative in November 1977.

reasonable and rational than no-bias subjects and as less emotionally extreme in the directions of toughness, tenderness, and level of enthusiasm. (c) High-bias subjects responded more extremely than no-bias subjects to questions pertaining to their political views. On the other hand, no differences were found between the high-bias and no-bias groups in (a) responses to self-report scales (and subscales) measuring dogmatism, locus of control, defensiveness, and impulsiveness; (b) performance on the Embedded Figures Test; and (c) the content and direction of the subjects' political ideology. These findings are interpreted as being consistent with theoretical treatments of dogmatism as a style of thinking independent of ideology, even though they did not correlate significantly with the Dogmatism Scale.

The Embedded Figures Test and the rod-and-frame test had been constructed as performance measures of field dependence. Their relationship with the authoritarianism–dogmatism personality syndrome (as measured by self-report questionnaires) has been debated for over 20 years, with no clear resolution (see, for example, Ohnmacht, 1968; Rudin & Stagner, 1958; Witkin & Moore, Note 1). As to the relationship between performance on the Embedded Figures Test and susceptibility to biasing information, here again the reports are in conflict. McFall and Schenkein (1970) found a significant expectancy effect for field-dependent subjects but not for field-independent subjects, whereas in the present investigation high-bias subjects did not differ from no-bias subjects in their Embedded Figures Test performance. Moreover, the correlation between the Embedded Figures Test and the Dogmatism Scale on all 179 subjects in Study 2 did not reach statistical significance.

Another issue that has received lively debate over the years is whether authoritarianism is related to conservative and right-wing political ideology or whether this personality syndrome is independent of the *content* of the political ideology. Rokeach (1960) wrote quite convincingly about the "authoritarian of the left" (although his most famous piece of evidence was based on a sample of only 13 British communists), and the construction of the Dogmatism (D) Scale as a substitute for the original authoritarianism scale, the F scale, (Adorno, Frenkel-Brunswik, Levinson, & Sanford, 1950) was motivated (in part) by this conviction. More recently, the superiority of the D scale over the F scale with regard to left-wing ideology was put in serious doubt by Thompson and Michel (1972), who found that *both* F and D scales were significantly related to political conservatism and Christian traditionalism. There is a need for research directed at identifying measures that more adequately reflect cognitive styles theoretically related to authoritarianism and dogmatism.

The findings of Study 2 have some bearing on this issue. The tendency of the high-bias subjects toward the right-wing ideology was slight and insignificant, whereas their excess extremity in political view independent of its contentual direction was clear and statistically significant. Thus, if bias in scoring can be considered as one facet of dogmatism, Rokeach's argument that the trait of dogmatism is largely independent of the specific content of the political ideology is supported by these findings.

Conclusions

Bias in scoring was demonstrated and replicated.

It is indicated by the data that susceptibility to biasing information is related to a dogmatic style of thinking, but is independent of the content and direction of ideology.

The utilization of self-report personality questionnaires and scales with college students is highly questionable and problematic: There are grounds to suspect that *ideal* self-image responses are provided when *actual* self-image descriptions are asked for and that specific questionnaires and scales loaded with social desirability may be too transparent for college students, resulting in falsified responses.

In two experiments, subjects were required to observe and predict the behavior of a hypothetical "chooser" who made choices for him- or herself and for a hypothetical other in a series of decomposed games. The preference for outcomes, or social motivational orientation, of the chooser was preprogrammed and varied across conditions. Results of the experiments confirmed that subjects were more readily able to detect the outcome preferences of choosers who made choices according to individualistic or competitive choice rules than of choosers who behaved in a prosocial or negatively self-interested manner. Furthermore, the prediction data obtained from Experiment 2 revealed that subjects tended to perceive choosers' own gain as an important component of most of the choosers' secondary motivation. Evidence from subjects' ratings of the choosers' personality attributes and estimates of the relative weights the choosers attached to their own and the other's gain (Experiment 2) indicated that subjects formed distinctive impressions of the choosers despite differences in predictive accuracy across conditions. A third experiment, performed to investigate the relationship between predictive accuracy and the mathematical complexity of the choosers' various choice rules, found no evidence that mathematical complexity influenced subjects' performance on the prediction task.

The study of social exchange is concerned with situations where the outcomes of two or more individuals are dependent upon their mutual behaviors. Recent literature dealing with social exchange has focused on determining the values that individuals seek to maximize in outcome interdependence situations. McClintock (1972b), for example, has proposed that the value of outcomes to an individual may be defined by that person not only in terms of what he or she receives for self but also in terms of what others receive. Experiments by Messick and McClintock (1968), McClintock, Messick, Kuhlman, and Campos (1973), and Kuhlman and Marshello (1975) confirm that people show individual differences in their tendencies to maximize their own outcomes, joint outcomes, and the relative difference between their own and others' outcomes.

These preferences for outcomes, or social motives, have been formally characterized in a geometric model by Griesinger and Livingston (1973). The Griesinger and Livingston representation takes the form of a two-dimensional space where outcomes or payoffs to self are ordered along the horizontal axis, and outcomes to the other are ordered along the vertical axis. An actor's preference for certain distributions of points in this space is represented as a vector of infinite length extending from the origin. Thus, an individual-

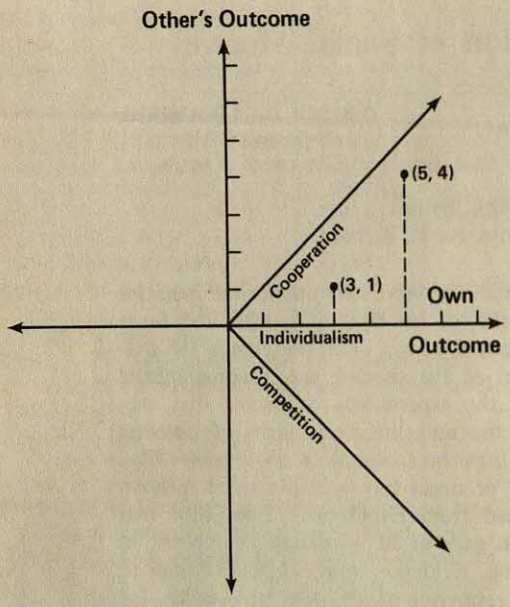

Figure 1. The Griesinger and Livingston vector representation of social motives. (Numbers in parentheses are examples of distributions of points to self and other.)

istic motive, or preference to maximize one's own gain, can be represented as a vector extending in the positive direction along the horizontal axis. The locations of the vectors representing cooperation (maximization of joint gain) and the competition (maximization of relative gain) are 45° removed from the horizontal in the counterclockwise and clockwise directions, respectively (see Figure 1).

Preference orderings for points in this outcome space are defined in terms of the magnitudes of their perpendicular projections on the actor's motivational vector. The greater the projection of a point, the more preferred is the associated outcome. For example, an individualistic actor might be presented with a choice between a point that affords self 5 units and the other 4 units and a point that affords self 3 units and the other one unit. As Figure 1 indicates, the point 5,4 is preferred to the point 3,1 because of its greater projection on the actor's motivational vector: Receiving 5 for self is better than receiving 4. However, if the actor is competitively oriented, 3,1 is preferred to 5,4 because it affords the actor greater relative advantage over the other (2 units as opposed to 1). The point 5,4 is preferred by a cooperative actor because it leads to the higher joint gain.

The previously cited work of McClintock, Messick, and their colleagues has led to the refinement of a method for assessing the social motivational orientations of experimental subjects utilizing a form of payoff representation known as the decomposed game. The decomposed game procedure involves simultaneously presenting both members of a pair of subjects with a series of two- or multichoice decision situations. Each of the choice alternatives in these situations affords a certain payoff to the subject and a certain payoff to another dyad member. Thus, each choice alternative in a decomposed game represents a point in self/other outcome space. Subjects are required to select their preferred alternative on each trial in ignorance of each other's behavior. Classification of subjects' motivational orientations is performed by comparing their patterns of choices in the decomposed games with those which would have been produced by actors displaying perfect consistency with the individualistic, cooperative, and competitive vectors.

This technique has two major strengths as a motive assessment procedure. First, while maintaining the essentials of outcome interdependence between subjects, the decomposed game minimizes the possibility that strategic considerations will influence the subjects' selections. Although each subject's choice affects both own and other's outcomes, neither subject can utilize his or her choices in an instrumental way to influence the other's choices. Second, the procedure allows the investigator to confront the subject with combinations of choices reflecting different outcome structures that are dominant in respect to the motives under consideration.[1]

[1] The dominance structure of a game is determined by examining which motives or values are maximized by particular choices. Suppose that an actor is presented with a decomposed game offering a choice between A, which affords the actor 50 units and the other 10 units, and B, which affords the actor 40 units and the other 30 units. Choice A will maximize both the actor's own gain and his or her relative gain. Choice B will maximize joint gain of the actor

The "Naive Psychology" of Social Motives

Although researchers have examined individual differences in motives and how they relate to subjects' observed laboratory game play (e.g., Kuhlman & Marshello, 1975), little empirical attention has been paid to the question of whether and how subjects, as "naive psychologists" (Heider, 1958), perceive the outcome preferences of others. Whenever outcome interdependence and the possibility of social influence exist, an actor intent on maximizing preferred outcomes must simultaneously take into consideration both own and other's goals, as well as the relative power of self and other (Thibaut & Kelley, 1959). Thus, in most settings of outcome interdependence, accurate information about the other's preferred outcomes should be instrumental in guiding the actor's attempts both to approximate directly preferred outcomes and to influence strategically the other's behavior.

Perception of motives in the Prisoner's Dilemma Game (PDG). One of the few investigations relevant to the topic of the naive perception of social motives was performed by Kelley and Stahelski (1970). They assessed the motivational orientations of subjects as cooperative or competitive by asking them about the goals they wished to maximize in the PDG. Subjects were then paired with other subjects who had expressed cooperative or competitive intent. Periodically, subjects' impressions of their partners were gathered during the course of PDG play. The results indicated that a competitive orientation on the part of the other was more readily perceived than a cooperative orientation. Further, although cooperative subjects were able to detect their partner's goals regardless of whether these goals were cooperative or competitive, competitive subjects often misjudged cooperative partners' goals to be competitive. Finally, when asked about the propensity of others to select the two PDG choices, the competitors indicated that the vast majority of people would be similar to themselves and opt for the competitive goal, whereas cooperators felt that some people would be like themselves and others would choose the competitive alternative.

Expectations concerning the goals of others in the decomposed game. The findings of a recent experiment conducted by Kuhlman and Wimberley (1976), however, suggest that the Kelley and Stahelski study may indicate more about the motivational structure of the PDG than about the beliefs that cooperators and competitors have concerning the relative predominance of these motivational orientations in the population. Kuhlman and Wimberly classified subjects as cooperative, competitive, or individualistic on the basis of their choices in a series of three-choice decomposed games. Since the desire to maximize relative gain and the desire to maximize one's own gain represent the two primary motivational reasons for "competition" in the PDG (McClintock, 1972a), the Kuhlman and Wimberley competitors and individualists correspond to a partition of Kelley and Stahelski's PDG competitors.

After making a series of decomposed game choices, subjects in the Kuhlman and Wimberley experiment were asked to estimate what proportion of other persons would make each of the three choices in four three-choice decomposed games having various dominance structures in regard to joint, relative, and own gain maximization. Also, subjects estimated the proportions of others who would make the cooperative and competitive choices in the PDG. Subjects then played 30 trials of a PDG against a uniformly cooperative or competitive other.

The results obtained on choice behavior in the PDG and subjects' estimates of others' choices in the PDG paralleled those of Kelley and Stahelski (1970). However, estimates of population choice proportions in the decom-

---

and the other. An example of a decomposed game with a different dominance structure is a situation in which the A choice affords 50 units for self and 20 units for the other and the B choice affords 40 units for self and 0 units for the other. Choice A maximizes (is the dominant choice with respect to) one's own and joint gain, whereas B maximizes relative gain. In the first example, the decomposed game has a similar motivational structure to the Prisoner's Dilemma Game (PDG); the latter example most closely resembles the Maximizing Difference Game (MDG; McClintock & McNeel, 1966).

posed games revealed different expectations about the preferences of others. Results from a game in which joint, own, and relative gain were each maximized by separate choices were particularly interesting. In this situation, cooperative subjects thought that the joint-gain maximizing choice would be the most popular followed by the own-gain choice and then the relative-gain choice. Competitive subjects' ordering of others' preferences was just the reverse of that of the cooperative subjects: relative gain followed by own and then joint gain. Individualistic subjects felt that the own-gain maximizing choice would be preferred by most and that the relative-gain maximizing choice would be slightly more popular than the joint-gain choice.

When considered together with the estimates for others' choices in the remaining decomposed games, these data suggest that each person may view her or his own motive as the modal orientation in the population. Recent work by Ross (1977) provides additional support for this interpretation. He observes that individuals who lacked good baseline data about typical behavior in a situation resorted to personal criteria to make predictions about others. In other words, one's own behavioral preferences are assumed to be more normative than nonpreferred tendencies.

Detecting the motives of others in the decomposed game. The previous research concerns how an actor's own motivational dispositions influence his or her attributions of motives to others. None of this research has asked the prior, perhaps more fundamental, questions of whether and how rapidly actors can make accurate attributions to various major dispositions, given that these dispositions are accurately and consistently represented in the behavior of another. Kelley (Note 1) terms such dispositional acts as motivational moves with "action-immediate consequences," that is, behaviors for which an observer can make a direct attribution concerning an actor's goal in regard to the actor's own and another's outcomes.

The major purpose of the studies to be reported was to determine whether and how rapidly actors can make consistent and accurate attributions regarding different classes of social motives. Subjects in Experiments 1 and 2 were required to observe and predict the behavior of a hypothetical person called "the chooser," who made choices consistent with a particular motivational vector across a series of decomposed games. The use of the decomposed game format made it possible to represent various motivational choice vectors in a relatively systematic and unambiguous way. Further, the hypothetical person's choices were made in a context where he or she had complete control over own and some other person's outcomes. Hence, the observer or subject had no reason to anticipate that the hypothetical person was making choices for strategic reasons, that is, to influence the other to behave differently at some subsequent point in time. In effect, then, the hypothetical person was portrayed as making motivational moves with action-immediate consequences. And it was the observer's task to detect the nature of these motivational moves.

A second purpose of the first two experiments was to explore subjects' impressions of actors behaving according to different motivational rules. The overwhelming majority of impression-formation studies have focused on impressions of individuals described by a series of personality trait adjectives. There is a paucity of information, however, about the dispositional information that overt behaviors convey. The lack of such information is unfortunate, since behaviors are theorized to play a central role in the attribution of dispositions (Jones & Davis, 1965). Dispositional attributions, if they deal with stable characteristics of an actor's orientation toward self and others, should in turn be significant predictors of an observer's reactions to the actor in outcome interdependence situations.

Of particular interest to the present investigation is whether choice behavior consistent with a particular motivational vector results in impressions that distinguish the actor from other actors who have different outcome preferences. To find out in what ways impressions might differ, subjects in Experiments 1 and 2 rated the chooser on bi

polar adjective scales immediately following their observations and predictions of the chooser's choices.

Finally, since each motivational vector is defined by a different set of mathematical operations in regard to one's own and the other's outcomes (e.g., maximization of relative gain implies the algebraic operation of subtracting other's outcomes from own outcomes, whereas joint gain implies adding own and other's outcomes), a third study was conducted to determine whether the rate of detecting a particular vector was related to its mathematical as well as its social properties.

Experiment 1

The major hypothesis of Experiment 1 was that subjects would experience greater difficulty predicting the choices made by a chooser who placed equal or greater value on other's outcomes (i.e., behaved prosocially) than a chooser who placed higher value on own rather than other's outcomes (i.e., behaved in a self-centered manner). This finding was anticipated on the basis of previous studies that have demonstrated the pervasiveness of self-centered choice behavior in laboratory outcome interdependence situations (e.g., McClintock & McNeel, 1966; McClintock & Moskowitz, 1976).

In order to get some idea of the generality of the predictions of the hypothesis, a range of motives was examined. In addition to the motivational vectors of cooperation, individualism, and competition, the prosocial motive, altruism (maximize other's gain), was included in the design. Three other conditions corresponded to vectors falling midway between pairs of these "pure" motives (i.e., altruism/cooperation, cooperation/individualism, and individualism/competition; see Figure 2). Thus, in three out of seven conditions, namely, altruism, altruism/cooperation, and cooperation, the chooser met the criterion of demonstrating as much or greater concern with other's outcomes as with own outcomes. Poorer predictive accuracy was expected in these conditions than in the remaining conditions, where the chooser valued own outcomes more highly than other's.

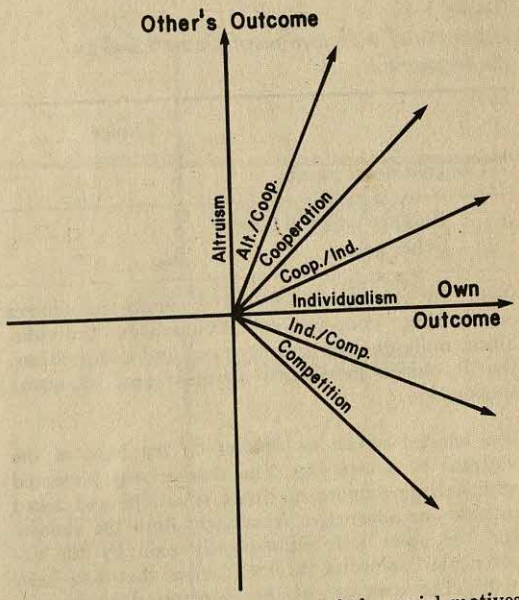

Figure 2. Vector representation of the social motives studied in Experiment 1.

Method

Subjects. The subjects were 70 introductory psychology students (29 males, 41 females) at the University of Alberta, Canada. All subjects received course credit for their participation. Subjects were randomly assigned to observe and predict a chooser having one of the seven social motives described previously.

Stimuli and apparatus. The stimulus materials consisted of two-choice decomposed games. Decomposed game situations were presented, responses were made, and feedback was given at a standard teletype connected to a PDP8/I computer. Payoffs to the chooser and the other in every decomposed game trial were randomly selected by a computer subroutine from the digits 0 through 9. The correct choice on each trial was determined according to which of the randomly generated chooser–other alternatives had the largest projection on the chooser's motivational vector. It is important to note that the correct choice often satisfied both the particular chooser's motive and one or more of the other motives also being investigated in the study. How many other motives and which other motives were also satisfied by the chooser's choice varied from trial and trial. An example of a decomposed game as it appeared to subjects is shown in Table 1.

Procedure. After subjects were brought to the experimental room, they were informed that the experiment was concerned with how well one could predict another person's behavior and the kinds of impressions formed of the person. Subjects were told that during the previous year, pairs of students had been brought to the lab. One member of each pair

Table 1
Example of a Decomposed Game Used in Experiment 1

Designation of points	Choice A	Choice B
Chooser gets	5	1
Other gets	3	6

Note. In this example, the A choice maximizes cooperation, cooperation/individualism, individualism, individualism/competition, and competition; the B choice maximizes altruism and altruism/cooperation.

was selected to act as chooser on the basis of the outcome of a coin flip. The chooser was presented with a large number of choice situations and asked to pick one alternative from each. Both the chooser and the other were subsequently paid by the experimenter according to the choices that had been made. The structure of the decomposed games was then explained, and subjects were told that during the experiment their task would be to predict, as best they could, what the chooser chose in each situation.

Three practice trials were provided (without feedback) to acquaint the subjects with the manner in which the situations would be be presented on the teletype and the manner in which the subjects were to enter their responses. Following the practice trials, subjects predicted the chooser for a total of 40 trials. On the first 10 of these trials, no feedback was provided about the correctness of predictions. After the 10th trial, feedback was introduced. The pace of the experiment was controlled by the subject's rate of responding.

Upon completion of the last trial, subjects evaluated the personality attributes of the chooser on 30 9-point bipolar adjective scales: young–old; unCanadian–Canadian; bad–good; active–passive; weak–strong; cooperative–competitive; rational–irrational; peaceful–warlike; conservative–liberal; immoral–moral; religious–unreligious; rich–poor; stable–unstable; untrustworthy–trustworthy; honest–dishonest; impolite–polite; selfish–unselfish; cruel–gentle; calm–agitated; wise–stupid; kind–unkind; usual–unusual; unpredictable–predictable; serious–humorous; unfriendly–friendly; sociable–solitary; timid–courageous; masculine–feminine; insincere–sincere; and tolerant–intolerant. These scales were selected both on the basis of general interest and on their potential ability to discriminate among the choosers along psychologically meaningful dimensions, as suggested by the factor-analytic work of Osgood, Suci, and Tannenbaum (1957) and Kuusinen (1969).

Results

The average number of times subjects correctly predicted the chooser in each block of 10 trials is shown in Figure 3. The figure pro
vides support for the hypothesis: Subject
were better at predicting individualistic
through-competitive choosers than coopera
tive-through-altruistic choosers. Overall, th
former choosers were predicted accurately o
about 83% of the trials, whereas for the lat
ter choosers, the accuracy rate was only 66%

Two separate analyses of variance were
performed after submitting the proportion o
correct predictions for each subject on each
trial block to an arc sine transformation. In
the first analysis, performance on the first
block of 10 trials when no feedback was
given to subjects was compared with mean
performance on the subsequent feedback trials.
Significant main effects were obtained for
chooser motive, $F(1, 63) = 6.10$, $p < .001$,
and feedback, $F(1, 63) = 21.09$, $p < .001$, as
well as a significant Motive × Feedback in-
teraction, $F(6, 63) = 3.16$, $p < .01$. An ex-
amination of Figure 2 indicates that while
accuracy increased in the competitive, altru-
istic, and individualistic/competitive chooser
conditions with the introduction of feedback,
the accuracy for cooperative and altruistic/
cooperative choosers declined slightly. The
second analysis, performed on the three
blocks of trials in which subjects received
feedback, once again yielded a significant
main effect for motive, $F(6, 63) = 7.92$, $p <$
.001. There was also a significant effect for
trial blocks, $F(2, 126) = 13.93$, $p < .001$, in-
dicating that subjects improved their per-
formances with practice. The Motive × Trial
Blocks interaction, however, was not signifi-
cant, $F(12, 126) < 1$. An a priori contrast
performed on the overall accuracy achieved
on feedback trials between those who ob-
served altruistic, altruistic/cooperative, and
cooperative choosers versus cooperative/indi-
vidualistic, individualistic, individualistic/
competitive, and competitive choosers indi-
cated a statistically reliable difference between
these two groups, $t(63) = 6.66$, $p < .001$.

To determine the extent to which observers
formed similar or dissimilar impressions of
the choosers whom they observed, the ob-
tained personality attribute ratings were sub-
mitted to a discriminant function analysis
(Tatsuoka, 1970). Discriminant function

analysis is a multivariate statistical technique that finds the set of uncorrelated, weighted linear combinations of predictor variables that maximally discriminates among individuals classified according to some grouping variable. In this study, groups consisted of chooser-motive treatment conditions.

Of the discriminant functions that resulted from this analysis, only one reached statistical significance, Wilks lambda (180 = .0116, $p < .02$. This function accounted for 47.53% of the discriminatory power of the battery of derived functions. The locations of group means on the function or "centroids" are plotted in Figure 4.

Figure 4 indicates that subjects' ratings were able to discriminate among the choosers along a dimension roughly corresponding to social motivational orientation. While the ordering of centroids on this dimension is not isomorphic with the degree of the various choosers' prosocial intent, subjects' ratings of choosers discriminated between those with prosocial and those with self-centered outcome preferences. The larger discriminant coefficients obtained from the analysis indicated that higher ratings of agitation, stability, selfishness, unfriendliness, badness, masculinity, and—oddly enough—politeness tended to be associated with self-centered classification by this function.

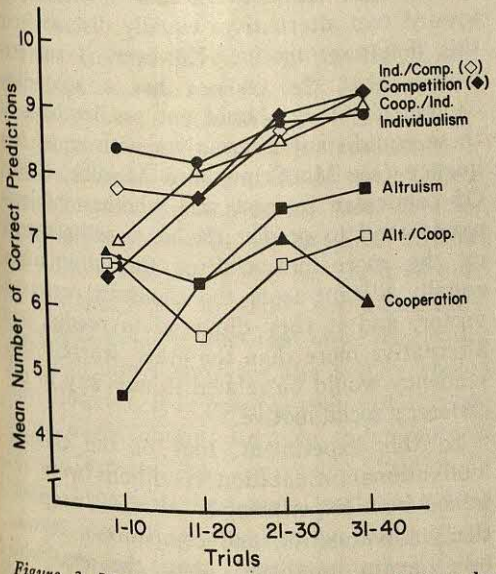

Figure 3. Mean number of correct predictions by chooser motive condition and trial blocks, Experiment 1.

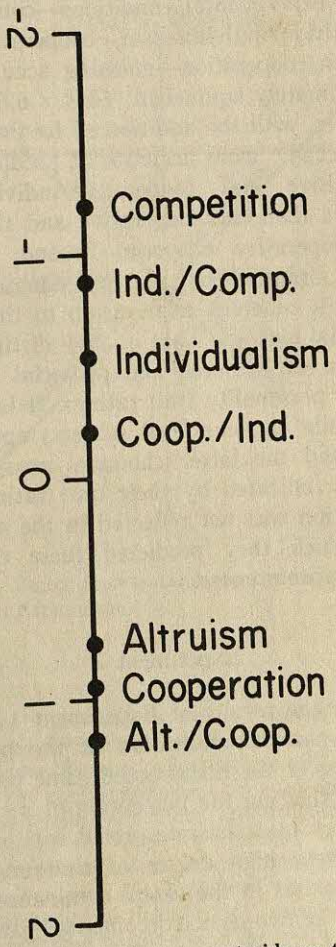

Figure 4. Location of group centroids on the significant discriminant function, Experiment 1.

Discussion

Two important findings emerged from this experiment. First, subjects were not uniformly accurate at predicting the outcome preferences of actors. In a third-party prediction task, the social motivational orientations of self-centered choosers were more readily detected than those of prosocial choosers. This finding is particularly interesting if considered in the light of subjects' performance on the initial no-feedback trials, which amounted to guessing the choosers' preferences. In four

of the experimental conditions—competition, competition/individualism, cooperation, and altruism/cooperation—guessing accuracy was approximately equivalent, (Ms = 6.6 to 7.0). However, with the addition of feedback, subjects became more accurate at predicting the competitive and cooperative/individualistic choosers than the cooperative and the altruistic/cooperative choosers. Second, subjects formed impressions of the choosers that showed a coherent relationship to the choosers' social motives. That is, they distinguished between self-centered and prosocial choosers in their personality trait ratings. It is curious that while at some level subjects apparently recognized the latter choosers' prosocial intent, as indicated by their trait ratings, this recognition was not reflected in the accuracy with which they predicted these choosers' outcome preferences.

Experiment 2

While the results of Experiment 1 are encouraging as an indication of the potential usefulness of the decomposed game technique for investigating the perception of social motives, they must be interpreted with caution. A relatively high degree of confounding of motives exists in the choice-dominance structures of the two-choice decomposed game. Depending upon the particular configuration of chooser's and other's payoffs in the situations employed as stimuli in Experiment 1, anywhere from one to all seven of the motivational vectors that were being investigated could have been represented by the same decomposed game choice. The most precise diagnostic information about the chooser's motive (from a mathematical standpoint) should have been communicated in decomposed games in which the alternative selected by the chooser was not the same as the alternative preferred by choosers with any of the other motivational orientations under study. However, this special situation could only have occurred in Experiment 1 when the chooser's motive was altruism or competition. Even under this circumstance, the situation would be expected to occur relatively infrequently because of the random nature of the computer-generated decomposed game entries. Thus, it is unclear to what extent subjects in every condition of Experiment 1 received equivalent amounts of information and whether it was in a sufficiently unconfounded form to permit them to accurately locate the chooser's motivational vector.

The purpose of Experiment 2 was to extend and replicate the findings of the previous study. In this experiment, the decomposed game observation and prediction paradigm of Experiment 1 was used but modified in order that the degree and nature of the confounding of motives could be precisely specified and controlled across conditions. Like the previous study, the issues of whether choice patterns consistent with different motivational vectors are perceived by subjects with differential accuracy and whether variations in social motivational orientation influence impression formation were of primary interest.

In addition, however, Experiment 2 was also concerned with subjects' reactions in situations where an actor's dominant choice vector is not represented among the decomposed game choices, but the two immediately adjacent choices are represented. If an actor is assumed to be motivated by only a single vector, then the actor should be indifferent toward two alternatives equally distant from this dominant motive. However, if subjects believe that the chooser has a secondary choice rule, they should not predict both of these equidistant alternatives with equal frequency (see MacCrimmon & Messick, 1976). Of particular interest was whether subjects would tend to predict the more self-centered or the more prosocial of the alternatives equally distant from the chooser's preferred vector, and if they did tend to predict one alternative more than the other, whether this tendency would be related in any way to the chooser's social motive.

In this experiment, four of the chooser motivational orientation conditions were retained from Experiment 1—altruism, cooperation, individualism, and competition. It was once again predicted that choosers who adopted an individualistic or competitive goal would be more accurately predicted than

choosers who made choices consistent with an altruistic or cooperative goal. As well as the vectors just noted, four motivational vectors not previously investigated were included in the design of Experiment 2—aggression (minimize other's gain), martyrdom (maximize other's relative gain), masochism (minimize own gain), and sadomasochism (minimize joint gain). The inclusion of these additional vectors permitted a more general test of the hypothesis that self-interested motives are the most accurately perceived. Figure 5 shows the locations of these vectors in own–other outcome space.

Although seldom observed in laboratory gaming situations, aggression undoubtedly plays a significant role in many real-life outcome interdependence situations. Studies conducted by Davis (1972) suggest that an aggressive preference on the part of an actor is often interpreted as a symptom of a competitive nature. Aggression differs fundamentally from martyrdom, masochism, and sadomasochism in that one's own gain receives greater weight (zero) than the other's gain (negative) in determining outcome preference. Thus, it was anticipated that subjects would experience relatively little difficulty in predicting an aggressive chooser and that accuracy would resemble that observed for other self-centered motives.

The vectors of martyrdom, masochism, and sadomasochism are rare not only in laboratory games but also in real life. Despite their abnormal status among social motives, subjects' relative abilities to detect them are of theoretical interest. To the extent that an actor repeatedly behaves in an atypical fashion (i.e., displays a preference for negative over positive outcomes to self), an expectancy hypothesis would predict that observers would have difficulty identifying the actor's choice rule. However, it is possible that just the opposite might obtain. Because these motives violate expectations concerning "rational" choice behavior, they may tend to arouse greater interest or attention on the part of observers and, hence, may potentially be detected more readily than those motives which affords the self greater positive outcomes.

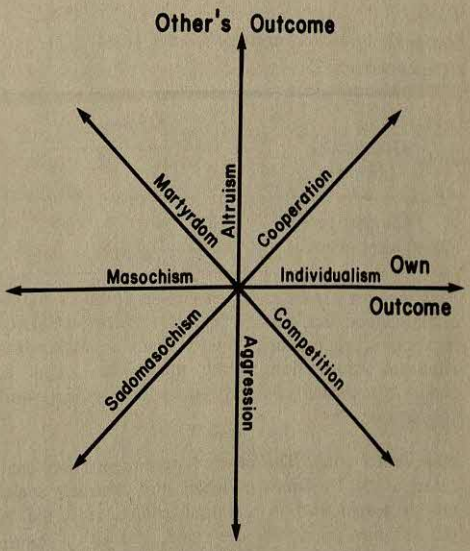

Figure 5. Vector representation of the social motives studied in Experiment 2.

Method

Subjects. The subjects were 89 female introductory psychology students at the University of California, Santa Barbara, who participated in the experiment in partial fulfillment of a course requirement. The number of subjects who watched choosers with each of the eight motivational orientations varied between 10 and 12. An additional 12 subjects were run but were discarded from the analysis for reasons of equipment failure (10), experimenter error (1), or failure to understand the instructions (1).

Stimuli. Subjects alternately observed the chooser make choices then predicted the chooser's behavior, without feedback, in a series of four-choice decomposed games (see Table 2). An observation/prediction trial block consisted of a total of 8 observation trials followed by 12 prediction trials. This observation/prediction sequence was repeated five times in the course of the experiment. Although the observation/prediction format differed from that used in Experiment 1, no differences in the direction of the findings were expected.

The eight decomposed games presented during the observation trials contained one choice that was dominant in terms of the chooser's motivational orientation. Games were constructed in a manner such that this dominant alternative maximized *only* the chooser's motive in 25% of the games. In the remaining 75%, this dominant choice not only maximized the chooser's motive but also two neighboring motives (motives falling within 90° of the chooser's vector).

Motivational structures of 8 of the 12 decomposed games presented during the prediction trials were the same as the 8 games presented during the

Table 2
Example of a Decomposed Game Used in Experiment 2

Designation of points	Choice A	B	C	D
Chooser gets	2	4	1	6
Other gets	1	0	3	1

Note. In this example, the A choice uniquely maximizes sadomasochism; the B choice uniquely maximizes aggression; the C choice maximizes altruism, martyrdom, and masochism; the D choice maximizes competition, individualism, and cooperation.

observation trials. The other 4 prediction trials consisted of (a) 2 games in which the chooser's social motive would lead to a unique choice, as it did in the 8 games previously described, and (b) 2 games in which there was no unique choice consistent with the chooser's motive, but rather the chooser's motive was equally satisfied by two outcomes representing maximal projections on the motivational vectors immediately adjacent to the chooser's vector. Inclusion of the latter games in the prediction trials provided a means for examining subjects' beliefs about the choosers' possible secondary motives.

Payoffs on all games were randomly transformed so that no two situations looked identical to subjects. Thus, accurate predictions could not be made by rote memorization of the observation trials.

Procedure. From one to four subjects participated in each experimental session. Upon their arrival, subjects were placed in individual cubicles. Each of these cubicles was equipped with a TV monitor and a response box with four letters labeled A through D. The instructions, presented on videotape, were read by a male graduate student.

Subjects were instructed that the purpose of the experiment was to develop a test of "social intelligence" that would measure a person's relative ability to understand and predict the behavior of another person. It was explained that they would be required to first observe and then predict the behavior of a person called "the chooser" in some simple choice tasks in which the chooser would make choices for self and for a person called "the other." No information about the other was provided, aside from the fact that the other was affected by the chooser's behavior. In an attempt to motivate subjects to be accurate, a reward of $25 was to be given to the subject in the study who made the most correct predictions. In addition, each subject was told that she would receive group and individual performance feedback. All of these promises to subjects were ultimately kept in a debriefing letter.

A sample decomposed game was then presented and the nature of the payoffs explained. Subjects were told that the payoffs were in cents and that they were to assume that these cents came from a bowl with an unlimited number of pennies. When the chooser made a choice that resulted in a positive payoff to self and or other, pennies were presumably extracted from the bowl. When either the chooser or the other got a negative payoff as a result of the chooser's choice, the party or parties who received the negative payoff returned the appropriate number of cents to the bowl. The reference to a bowl with an unlimited number of pennies was introduced to reduce the likelihood that subjects would interpret the situation as zero-sum (Rapoport, 1966).

During the first part of the experiment, blocks of observation and prediction trials were clearly segregated by segments of blank videotape and appropriate warning messages: "In five seconds the observation (prediction) trials will begin." On each observation trial, subjects first saw the decomposed game, and then, after a brief pause, the letter of the chooser's choice was displayed along with the decomposed game choices. Prediction trials were similar to observation trials except that the word *prediction?* appeared beneath the decomposed game instead of the letter of the chooser's selected alternative. No feedback was provided. Subjects were allowed approximately 5 sec in which to indicate their predictions by pressing the appropriate button. All responses were recorded by an Esterline-Angus event recorder.

Following the observation and prediction trials, subjects were given a questionnaire similar to that used in Experiment 1, which asked them to evaluate the chooser's personality attributes on 22 9-point bipolar adjective scales. These included 16 scales that were selected from among the items used in Experiment 1 because the mean ratings received by the choosers in the previous experiment exhibited a range of at least 2.5 scale points: calm–agitated; weak–strong; rational–irrational; religious–unreligious; impolite–polite; bad–good; usual–unusual; insincere–sincere; active–passive; cooperative–competitive; peaceful–warlike; stable–unstable; selfish–unselfish; kind–unkind; masculine–feminine; and

Table 3
Mean Percentage of Correct Predictions, by Chooser Motive Condition, in Experiment 2

Condition	% correct predictions
Individualism	78.8
Cooperation	64.1
Altruism	58.8
Martyrdom	41.1
Masochism	51.1
Sadomasochism	28.8
Aggression	65.0
Competition	74.7
Chance	29.2

unfriendly–friendly. Six new scales (punishes self–punishes other, hateful–loving, unfair–fair, ungenerous–generous, unconfident–confident, just–unjust) were added.

Subjects also estimated the weights that the chooser placed on own gain and other's gain on separate 9-point scales, which ranged from 1, "Chooser wanted to avoid giving cents to self (other)," to 9, "Chooser wanted to give as many cents to self (other) as possible."

Results

The overall mean percentages of correct predictions made by subjects in each condition are shown in Table 3. Figure 6 shows the mean number of correct predictions plotted over prediction trial blocks. For analysis of variance (ANOVA) purposes, those prediction trials for which there were two possible correct responses were omitted. (The results for these trials will be discussed later.) For ease of computation, subjects were randomly eliminated from conditions in which the number of observers exceeded 10. In addition, prior to performing the ANOVA an arc sine transformation was once again performed on the proportion of correct responses made by each subject on each block of prediction trials.

The results of the analysis revealed significant main effects for chooser motivational orientation, $F(7, 72) = 5.955$, $p < .001$, and trial blocks, $F(4, 288) = 8.076$, $p < .001$. As Table 3 and Figure 6 indicate, individualism and competition proved to be the easiest motives for subjects to detect, followed by aggression, cooperation, and altruism. Masochism, martyrdom, and sadomasochism posed the most difficulty, with subjects exposed to the sadomasochistic chooser performing at no better than the chance level. While there was a general trend toward improvement over the course of the chooser observation and prediction phase, as indicated by the significant trial blocks effect, the rate of improvement in accuracy did not differ appreciably across conditions: The Motive × Trial Blocks interaction did not reach statistical significance, $F(28, 288) = 1.102$.

Like the results of the overall ANOVA, a planned comparison designed to replicate the comparison performed on the data of Experiment 1 supported the original findings. The predictive accuracy of those who watched a

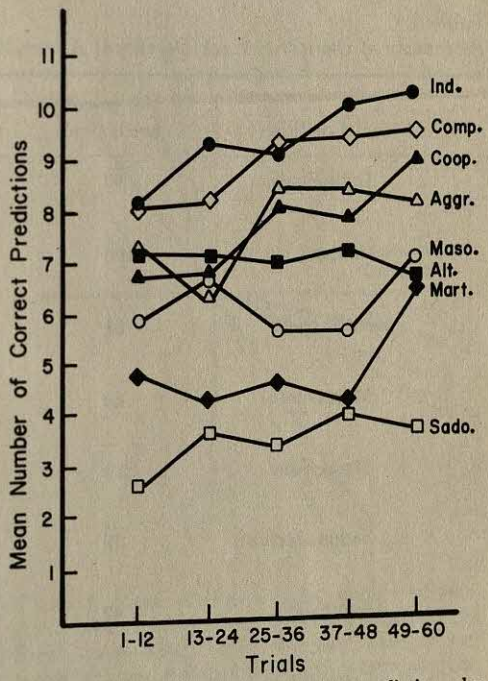

Figure 6. Mean number of correct predictions by chooser motive condition and trial blocks, Experiment 2. (Ind. = individualism; Comp. = competition; Coop. = cooperation; Aggr. = aggression; Maso. = masochism; Alt. = altruism; Mart. = martyrdom; Sado. = sadomasochism.)

cooperative or altruistic chooser was significantly poorer than those who watched an individualistic or competitive chooser, $t(72) = 2.43$, $p < .02$. A second planned comparison, between conditions in which the chooser assumed a choice rule in the motivationally "normal" range (i.e., altruism, cooperation, individualism, competition, aggression) versus conditions in which the chooser's social motive might be considered abnormal (i.e., martyrdom, masochism, and sadomasochism), demonstrated the existence of a significant difference in favor of higher accuracy on the part of subjects who watched the former types of choosers, $t(72) = 5.30$, $p < .001$.

Examination of subjects' biases concerning the choosers' possible secondary motives was performed by first counting the number of times that subjects made correct predictions on the total of 10 trials in which the decomposed game situation gave the chooser two dominant choice alternatives, then determining how often each of these two choices was

Table 4
Percentage of Choices of Each Dominant Alternative in "Chooser Indifferent" Prediction Trials

Condition	No. correct predictions	Choice	Z value
Individualism	99	76% competition 24% cooperation	5.20**

predicted by the subjects. The results are shown in Table 4. From the table it is evident that there was a tendency on the part of subjects to predict that the chooser would prefer the alternative favoring self-interest as opposed to the other's interest when confronted by two choices equivalent in terms of their actual dominance.

To summarize, the prediction phase of Experiment 2 provided a general replication of Experiment 1, yielding three main findings. First, the farther the chooser's motive was from own or relative gain maximization, the less readily it tended to be detected. Second, there was no evidence to suggest that the atypicality of motivational vectors affording negative outcomes to self in any way facilitated their recognition. Finally, there appeared to be a general expectation among subjects that the chooser would behave in such a way as to further self-interest when faced with a choice between two presumably equally attractive alternatives, although this expectation became less pronounced the farther the chooser's actual choice rule was from individualism or competition.

Analysis of the ratings of choosers collected during the impression phase of the study also produced results basically similar to those of Experiment 1. A discriminant function analysis performed on the ratings resulted in a single significant function, accounting for 48.26% of the discriminatory power of the battery of derived functions, Wilks lambda(154) = .0359, $p < .001$.

Figure 6 indicates that choosers again roughly ordered themselves from self-centered to other-centered along the dimension defined by the discriminant function, but this time clustered into three rather than two groups. Choosers with the most negative discriminant scores—the individualistic, competitive, and aggressive choosers—were those who weighed their own gain more highly than the other's gain. The most positive discriminant scores were obtained by choosers who valued the other's gain above their own gain—the altruist, the masochist, and the martyr. Inter-

mediate between these two extremes were the sadomasochistic and cooperative choosers, who had in common the characteristic of treating self and other alike (and in the long run, equitably). (See Figure 7.)

This time the larger discriminant coefficients indicated that "self-centered" classification tended to be negatively associated with perceived politeness, passivity, generosity, and kindness, and positively associated with perceived agitation, other punitiveness, stability, selfishness, and justness. Differences between this function and the function obtained in Experiment 1 could be due to differences both in the sample of adjective scales used for rating the chooser and in the range of stimulus motives investigated in the two experiments.

Figure 7. Location of group centroids on the significant discriminant function, Experiment 2.

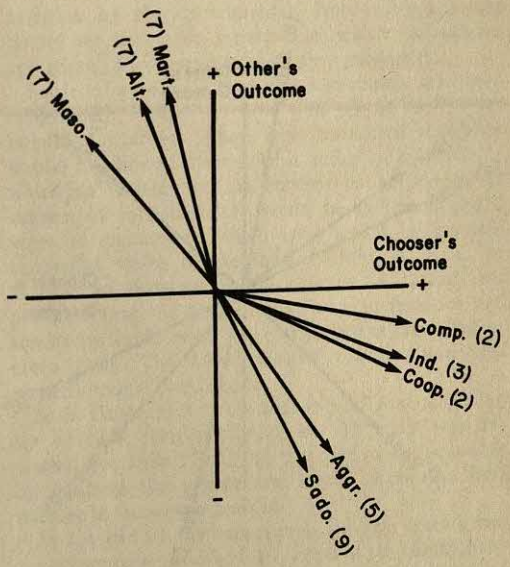

Figure 8. Mean observer-assigned vectors of inaccurate observers, Experiment 2. (*ns* are in parentheses. Maso. = masochism; Alt. = altruism; Mart. = martyrdom; Comp. = competition; Ind. = individualism; Coop. = cooperation; Aggr. = aggression; Sado. = sadomasochism.)

Finally, subjects' direct estimates of the weights that the choosers placed on their own and the other's gain were examined. Since it was anticipated that the ability to accurately estimate these weights might be related to a subject's success at predicting the chooser, weight estimates of accurate and inaccurate observers were considered separately. An accurate observer was defined as a subject who made at least 9 out of 12 correct predictions on the last prediction trial blocks. Subjects who made 8 or less correct predictions were classified as inaccurate. Mean observer-assigned weights were transformed by subtracting 5, to give the transformed scale a zero midpoint. Vectors derived from these mean assigned weights are shown in Figures 8 and 9 for inaccurate and accurate observers, respectively.

From Figures 8 and 9, it is evident that observers who accurately predicted the chooser on the last trial block were also more accurate in estimating the relative weights that the chooser placed on own and other's gain. For the accurate observers, the ordinal placement of the eight vectors corresponding to

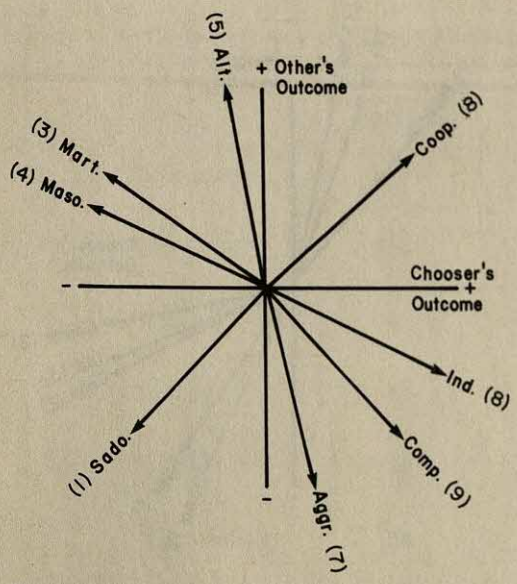

Figure 9. Mean observer-assigned vectors of accurate observers, Experiment 2. (*n*s are in parentheses. Sado. = sadomasochism; Maso. = masochism; Mart. = martyrdom; Alt. = altruism; Coop. = cooperation; Ind. = individualism; Comp. = competition; Aggr. = aggression.)

the eight chooser motivational orientations paralleled the correct order. However, several errors in the ordinal placement of these vectors occurred for the inaccurate observers. Both accurate and inaccurate observers exhibited a tendency to assimilate the relative weights assigned to the masochistic and the altruistic choosers toward martyrdom. Similarly, there was a tendency for the relative weights assigned to the aggressive and individualistic choosers to be assimilated towards competition. In the case of inaccurate observers, this latter assimilative tendency also held for the weight estimates of observers who viewed the cooperative and sadomasochistic choosers.

Prior to discussing the results of these first two studies, we will describe a third study that asked whether the rate of detecting a particular motivation vector was related to its mathematical properties.

Experiment 3

A few studies have investigated concept learning tasks that bear a resemblance to the present chooser prediction paradigm. In these experiments, the subject is typically required to make interval-level responses to a series of stimuli that vary on one or more attribute dimensions. In order to attain a reasonable level of accuracy, the subject must come to identify which of the stimulus attributes are relevant to the response, to correctly assign a relative weight to each of these attributes, and to identify the direction of the correlation between each relevant attribute and the response dimension.

The chooser prediction task of Experiments 1 and 2 is similar to an interval-concept learning problem, because subjects must decide whether one or both of two attributes, chooser's payoff and other's payoff, are relevant to determining the chooser's value for outcomes. Which of these attributes are actually important depends upon the motivational orientation of the chooser. To determine the value of outcomes for an individualistic chooser, for example, it is necessary to pay attention only to the chooser's payoff. However, both the chooser's payoff and the other's payoff must be taken into account when calculating the value of outcomes for a cooperative chooser. The relative weights placed on one's own outcome and the other's outcome and their signs (positive or negative) are shown in Table 5 for each of the chooser motivational orientation conditions of Experiment 2.

Experiment 3 was concerned with investigating the chooser prediction paradigm in the context of a nonsocial, interval-concept learn-

Table 5
Relative Weights Placed by Chooser on Own and Other's Outcomes, Experiment 2

Condition	Weight on own outcome	Weight on other's outcome
Individualism	+1	0
Cooperation	+1	+1
Altruism	0	+1
Martyrdom	−1	0
Masochism	−1	−1
Sadomasochism	−1	−1
Aggression	0	−1
Competition	+1	

ing task. In order to study just the mathematical component of the prediction task, references to a chooser making choices for self and other were deleted from the instructions and the decomposed game matrices.

The findings of previous studies indicate that subjects are better at interval-concept learning when relevant attributes are few as opposed to many (Azuma & Cronbach, 1966). In addition, variation in the relevant distribution of weights over attributes affects response accuracy. Uhl (1963) varied the predictive validities of three attributes and found a nonmonotonic relationship between subjects' response accuracy and relative weight disparity. Overall, subjects performed poorly when there was slight disparity among attribute weights, improved their accuracy when attributes were equally valid, and showed the best performance when there was a large discrepancy among weights. On the basis of these findings, it was hypothesized that subjects would find the nonsocial version of the chooser prediction task easier in conditions where one of the outcomes received a weight of zero than in conditions where both outcomes were equally important in determining an alternative's value.

Although it was recognized that the task involves making an ordinal comparison of alternatives to determine which is most highly valued, in addition to the interval judgment of the value of each alternative, this ordinal component was not expected to differentially affect accuracy across conditions in the nonsocial version of the task employed in this experiment.

Method

Subjects. The subjects were 64 introductory psychology students (13 males, 51 females) at the University of California, Santa Barbara. Eight subjects were randomly assigned to serve in each condition. All subjects received course credit for their participation.

Stimuli. A series of decomposed games identical to that used in Experiment 2 was employed. The situations were referred to as "matrices" in all instructions to subjects, and the words *Blue* and *Green* were substituted for the words *Chooser gets* and *Other gets* in the matrix display.

Procedure. Subjects arrived at the laboratory in pairs and were seated on the opposite sides of a partition by the experimenter. Both subjects could clearly see the video monitor on which instructions and stimuli for the experiment were presented.

Subjects were told that the experiment was concerned with finding out how well people could learn numerical concepts. They were instructed that they would be shown alternately a series of matrices in which an instance of the concept to be learned (a column of each matrix) would be indicated and a series of matrices in which they would be required to predict which of the four columns, A, B, C, or D, was an instance of the concept. A "hint" was provided that the column that was an instance had something to do with the entries in the blue and/or green rows. The terms *matrix, column,* and *row* were thoroughly explained.

As in Experiment 2, the sequence of first observing for 8 trials, then predicting for 12 trials was repeated five times. Subjects recorded their responses by marking the appropriate letter beside the trial number in an answer booklet.

At the end of the experiment, subjects were given a questionnaire designed to assess their comprehension of the concept. The questionnaire consisted of three parts. In the first part, subjects were asked to indicate whether for instances of the concept, the blue (green) numbers had tended to be larger, smaller, or neither larger nor smaller than the other blue (green) numbers in the matrix. Second, subjects were asked to write down the rule for deciding which column in a matrix was an instance. Finally, they were asked to fill in a blue number and a green number in a sample matrix where columns A, B, and C were given in such a way as to make column D an instance of the concept.

Results and Discussion

Table 6 gives the mean percentage of correct predictions across all trials for each condition in the present concept learning experiment. The figures for sister conditions in Experiment 2 are also shown.

A comparison between the Experiment 2 and the Experiment 3 results indicates that with the exception of the condition blue: −1–green: −1, the average accuracy for subjects in the social prediction task of Experiment 2 was higher (in some cases, quite substantially) than the average accuracy in the concept learning task.

Considering the accuracy figures for Experiment 3 alone, it is evident that the experimental hypothesis was not supported: There was no difference in performance on the task between conditions where either blue or green numbers received zero weight and conditions where both blue and green numbers

Table 6
Mean Percentage of Correct Predictions by Chooser Motive/Concept Condition, Experiments 2 and 3

Motive/concept	% correct predictions	
	Experiment 2 (motives)	Experiment 3 (concepts)
Individualism/blue: +1—green: 0	78.8	40.0
Cooperation/blue: +1—green: +1	64.1	37.5
Altruism/blue: 0—green: +1	58.8	30.7
Martyrdom/blue: −1—green: +1	41.1	31.3

Competition/blue: +1—green: −1	74.7	38.3
Chance	29.2	29.2

had nonzero weight. In support of this conclusion, an analysis of variance performed on these data after transforming them by the arc sine procedure yielded no significant main effect for condition, $F(7, 56) < 1$. A statistically demonstrable improvement in accuracy did occur across trial blocks, however, $F(4, 224) = 7.689$, $p < .001$.

The results obtained from the questionnaire administered at the end of the experiment indicated that few of the subjects in the experiment ever grasped the concept they were trying to learn. (Since the pattern of results appeared to be uninfluenced by condition, it will be described for all subjects.) Of the total of 64 subjects, 42, or approximately two thirds, failed to answer any part of the questionnaire correctly. Of the remaining 22 subjects, 19 were able to correctly generate an instance of the concept. However, because a large range of answers was potentially acceptable, it is not possible to determine how many of these 19 correct instances could be attributed to guessing. Subjects' performances were much poorer on the other two parts of the questionnaire than on the instance-generation question. Only 8 subjects managed to verbalize the rule, and only 6 subjects correctly identified the relative weights of both the blue and green numbers. In total, only 3 subjects answered the entire questionnaire correctly.

Thus, the results of the present experiment do not suggest that a relationship existed between the numerical complexity of the chooser's-choice rule and the subject's ability to predict the chooser in a social context. In fact, it appears safer to conclude the opposite: that the social context of the prediction task in the earlier studies facilitated learning of the mathematical aspects of the chooser's-choice rule.

General Discussion

The results of Experiments 1 and 2 have confirmed that variations in an actor's preference for outcomes affect the overall accuracy with which observers are able to predict the actor's choice behavior in a series of decomposed games. Although the preprogrammed choosers employed in these experiments exhibited perfect consistency in making selections from among sets of own/other outcome distributions, subjects nevertheless experienced difficulty in predicting the chooser's choices when he or she behaved in a negatively self-interested or prosocial fashion.

These data seem best interpreted from within an interaction-expectancy framework: The more popular a particular social motive is perceived to be as an interaction goal, the more likely it will be anticipated (and detected) in the behavior of others. Support for this assertion was obtained both from the accuracy data and from the existence of a self-interest bias in subjects' predictions of what the chooser would do when confronted with

paired rather than single alternatives dominant with respect to the chooser's motivational vector.

Expectations concerning the chooser's likely pursuit of self-interested goals appear to have been highly pervasive in influencing subjects' responses throughout the experiments. An examination of the performance of individual subjects indicated that most of them improved their accuracy in an incremental fashion rather than by the abrupt transition that might have occurred if the subjects had been systematically testing a range of alternative hypotheses about the chooser's motive. Subjects may have been reluctant to abandon a self-interest hypothesis even when it was less than perfectly valid. Confounding of motives within the choice-dominance structures of the decomposed games would allow subjects who held certain wrong hypotheses about the chooser (i.e., subjects who believed the chooser's motivational vector to be within 90° of his or her true vector) to still make some correct responses. Exacerbated by a tendency to pay more attention to instances of the chooser's behavior that confirmed a preference for self-interest than instances that provided disconfirmation (see Bourne, Ekstrand, & Dominowski, 1971), this explanation might account for some of subjects' conservatism in utilizing the information contained in the decomposed game choices made by prosocial and negatively self-interested choosers.

As we noted previously, it is curious that differences emerged in subjects' abilities to predict self-interested and prosocial choosers, considering that fairly distinctive impressions of the personality attributes of these two groups of choosers were formed. Researchers in the area of person perception have often stressed the importance of personality impressions, particularly first impressions, in determining our reactions toward others (Hastorf, Schneider, & Polefka, 1970). However, in Experiments 1 and 2 the impressions that were formed of prosocial and negatively self-interested choosers were apparently of little value to subjects in predicting these choosers' choice behaviors, even though choices to be predicted were of the same type as those upon which impressions were based.

One possible explanation for this apparent incongruity is that subjects' ratings of the choosers' personality attributes may have been retrospective reflections upon the choosers' choices, as opposed to impressions formed early in the course of observing the choosers. Whether the personality attribute ratings represent early or retrospective impressions, however, it is interesting to note the existence of groupings of motives in terms of both the discriminant function analysis of these ratings and the vector representations derived from the subject-estimated weights of Experiment 2. These groupings suggest that the psychological representation of motivational vectors may differ from their formal representation in terms of perceived angular distance, if not in their ordering.

Finally, Experiment 3 investigated the difficulty of learning various choice rules consistent with certain social motives outside of a social context. No evidence was obtained to suggest that the mathematical complexity of a given choice rule had any influence on increasing or decreasing an observer's ability to predict. Conversely, identifying the rule-detection task as a social one positively, though differentially, affected the likelihood of correct detection.

A major limitation of the present investigations is that they have provided little information about the factors that mediate the observed relationship between the chooser's social motive and the subjects' predictive accuracy. While observer expectations about the probability that an actor will adopt particular social motives provide an overall explantion for the results, other influences may have made important contributions to the present findings. For instance, the social motivational orientations of observers may have been a significant factor in determining their relative success at the prediction task. Subjects in the experiments described here exhibited a considerable degree of individual difference in their abilities to predict the various motives. If interaction expectancies are affected by one's own social motive, as the work of Kuhlman and Wimberley (1976)

would suggest, then it follows that this motive would influence the ability to detect others' social motives, especially others with motives identical to the observer's own orientation. Future research will consider this relationship.

Effects of External Evaluation on Artistic Creativity

Teresa M. Amabile
Brandeis University

This study examined the conditions under which the imposition of an extrinsic constraint upon performance of an activity can lead to decrements in creativity. Female college students worked on an art activity either with or without the expectation of external evaluation. In addition, subjects were asked to focus on either the creative or the technical aspects of the activity, or they were given no specific focus. Finally, some subjects expecting evaluation were given explicit instructions on how to make their artworks. As predicted, subjects in the evaluation groups produced artworks significantly lower on judged creativity than did subjects in the nonevaluation control groups. The only evaluation group for which this pattern was reversed had received explicit instructions on how to make artworks that would be judged creative. A possible reconciliation of these two disparate results is proposed, and practical implications are discussed.

In his autobiography, Albert Einstein describes a serious motivational problem he encountered during his student days: His physics examinations, forcing him to "cram all this stuff into one's mind" (Schilpp, 1949, p. 17), were so unpleasant that afterward he could not bring himself to consider scientific problems for an entire year. When he went on to advanced study in Zurich, he found ways to blunt the effects of educational constraint, "which smothers every truly scientific impulse" (p. 17). For example, he had a friend who agreed to work over the lecture materials so that Einstein would be freed from attending classes. In commenting upon this arrangement and its boost to his creativity motivation, Einstein later said,

> This gave one freedom in the choice of pursuits until a few months before the examination, a freedom which I enjoyed to a great extent and have gladly taken into the bargain the bad conscience connected with it as by far the lesser evil. It is, in fact, nothing short of a miracle that the modern methods of instruction have not yet entirely strangled the holy curiosity of inquiry; for this delicate little plant, aside from stimulation, stands mainly in need of freedom; without this it goes to wreck and ruin without fail. (p. 17)

Einstein's introspections and speculations about scientific inquiry are an elegant expression of the thesis to be advanced here: An intrinsically motivated state is conducive to creativity, whereas an extrinsically motivated state is detrimental. That is, if individuals engage in some activity primarily for its own sake, they will be most likely to produce creative work. If, however, they are led to engage in that activity as a means to achieve some salient extrinsic goal, their creative performance will be undermined.

This article is based on a doctoral dissertation submitted to the Department of Psychology, Stanford University. The research reported here was supported by Predoctoral Fellowship 5F31 MH05232-02, awarded to the author by the National Institute of Mental Health, and by two research grants to Mark R. Lepper: National Institute of Mental Health Grant MH-24134 and National Institute of Child Health and Human Development Grant HD-MH-09814.

The author gratefully acknowledges the advice and support of her dissertation committee members, Mark Lepper, Lee Ross, Daryl Bem, and Philip Zimbardo, and she wishes to thank several colleagues who offered comments and suggestions during various stages of the research and manuscript preparation: William DeJong, Susan Goldberg, Leslie McArthur, and Mick Watson.

The present conceptualization of creativity proposes that intrinsically motivated individuals will be deeply involved in the activity at hand because they will be free of extraneous and irrelevant concerns, concerns about goals extrinsic to the activity itself. They will be playful with ideas and materials because of their freedom to take risks, to explore new cognitive pathways, to engage in behaviors that might not be directly pertinent to attaining a "solution." Since they undertook the activity primarily for the enjoyment of engaging in it, they will see the activity as more like play than like work. Extrinsically motivated individuals, on the other hand, will be, at some level, concerned with the extrinsic goal to be attained and will thus not be as deeply involved in the activity. In addition, they will feel less free to engage in risk taking and will therefore rely more upon well-worn cognitive pathways. Finally, since they undertook the activity primarily for some reason extraneous to the activity itself, they will see it as more like work than like play.

Most recent intrinsic motivation research has been concerned with the "overjustification" hypothesis (Lepper, Greene, & Nisbett, 1973), derived from the attribution theories of Bem (1967, 1972), Kelley (1967, 1973), and deCharms (1968). This hypothesis states that if a person undertakes an interesting task under conditions that make salient to him the instrumentality of his behavior as a means to some extrinsic end, then that person will show less intrinsic interest in that activity later, when external constraints are absent, than a person who did not act under salient external constraints. Using the constraint-free measure of subsequent intrinsic motivation, results from a number of studies have supported this hypothesis (Amabile, DeJong, & Lepper, 1976; Condry, 1977; Deci, 1971; Kruglanski, 1975; Lepper & Greene, 1975; Lepper et al., 1973).

Recently, several theorists have begun to speculate about the effects of extrinsic constraint on *immediate* performance. In the formulation that is most relevant to the present research, McGraw (1978) has proposed a distinction between two different types of activities in terms of the differential effects that extrinsic constraint might have upon performance of those activities. McGraw describes tasks having *algorithmic* solutions as those for which the path to the solution is clear and straightforward; performance on these tasks should be enhanced by increases in extrinsic motivation. By contrast, creativity tasks require *heuristic* solutions, where it is difficult to immediately determine which operations would be relevant to a solution. Thus, creative performance should be adversely affected by increases in extrinsic motivation.

Direct Empirical Evidence

There is a handful of studies directly testing the hypothesis that decrements in creativity will accompany the imposition of extrinsic constraints. Of these, one was an overjustification study that included a measure of creativity in assessing the effects of extrinsic constraints (Kruglanski, Friedman, & Zeevi, 1971). In this experiment, one group of students was promised a reward for participation; for a second group, reward was not mentioned. Rewarded subjects produced less creative responses (as judged by two independent raters) during the experiment than did nonrewarded subjects; in addition, nonrewarded subjects later expressed greater enjoyment of the experiment.

Other studies provide further support for the proposed relationship between creativity and intrinsic motivation. In two experiments in which children made drawings under either reward expectation or no reward expectation (Greene & Lepper, 1974; Lepper et al., 1973), there was a tendency for rewarded children to produce more drawings, but of poorer quality (as judged by teachers), than nonrewarded children. A study of the effects of rewards on problem-solving performance (McGraw & McCullers, in press) found that rewarded subjects took significantly longer to break set in solving a Luchins water jar problem than did nonrewarded subjects. And in an elementary school setting (White & Owen, 1970), the creative performance of boys in a self-evaluation group was significantly higher than that of boys in peer-evaluation or teacher-evaluation groups.

While this research seems to support the intrinsic motivation view of creativity, studies within the behavior modification or token-economy traditions have obtained results that appear to contradict it. In one such study (Glover & Gary, 1976), children worked on a standard verbal creativity task in which points were awarded for fluency (number of different responses), flexibility (number of verb forms), elaboration (number of words per response), or originality (statistical infrequency of verb forms). Consistent with the experimental hypotheses, all four aspects of creativity were "demonstrated to be under experimental control" (p. 79); when fluency was rewarded, the children were fluent; when originality was rewarded, they were original; and so on. Under extinction, each aspect fell to baseline or below. Other studies of operant techniques, using both intersubject and between-group designs, have demonstrated functional control over creative performance (Halpin & Halpin, 1973; Johnson, 1974; Raina, 1968).

Thus, a cursory review of evidence on the effects of extrinsic constraint on creativity suggests a basic inconsistency in results. Overjustification studies have generally shown decrements in creativity under reward conditions, whereas behavior modification studies have shown increments under such conditions. However, as the results of the present study will suggest, a deeper analysis of the two paradigms leads to a possible resolution of the apparent contradiction.

The Present Study

A closer examination of the procedures used in the overjustification and behavior modification studies suggests that the key to their apparently contradictory results may lie in the type of instructions used. As suggested by the theoretical analysis of McGraw (1978), perhaps subjects will show decrements in creativity if extrinsic constraints are imposed, *unless* they are told specifically how to perform creatively. In order to examine this hypothesis, the present study attempted, within one experimental design, to show both decrements in creativity by an overjustification procedure *and* increments in creativity by a behavior modification procedure. In the former, a constraint was imposed upon subjects' engagement in an art activity, and they were given no specific performance instructions; in the latter, the same constraint was imposed upon subjects, and they were told specifically how to perform creatively. In accord with the intrinsic motivation model of creativity, it was expected that the simple overjustification groups—the groups working under extrinsic constraint, without explicit instructions on how to perform creatively—would show decrements, relative to control, in both creativity and intrinsic interest. And, as required by the theoretical argument developed here, it was expected that, although the specific-instructions group might show an increment in creativity compared to its control, it should not show a corresponding increment in intrinsic motivation. Thus, the major purpose of this study was to attempt a reconciliation of seemingly contradictory results by identifying those instructional sets under which extrinsic constraint might undermine creativity and those under which it might enhance creativity.

The specific extrinsic constraint employed in this study was the expectation of evaluation. Clearly, this constitutes an externally imposed constraint that is extrinsic to the activity itself; the external evaluation of an art product is not intrinsic to the activity of art itself. The use of this particular constraint is desirable for two reasons. First, expectation of evaluation has seldom, if ever, been used in previous overjustification research. As noted earlier, the extrinsic constraint usually employed is the promise of reward. Second, and most important, the external evaluation of products that may potentially be creative is so commonly employed in education and other settings as to be accepted as a fact of life. Thus, a demonstration of detrimental effects of evaluation could have significant practical implications.

Method

Design Overview

The experimental design employed here closely followed the usual overjustification paradigm: Subjects were either told or not told that their artworks

would be evaluated. Additionally, some subjects within each level of evaluation expectation were asked to focus on the creativity of their artworks; some were asked to focus on the technical aspects; others were not given any particular focus. Finally, two evaluation-expectation groups received specific instructions for performance: One was told how to make a technically good artwork, and one was told how to make a creative artwork.

Subjects

Subjects were 95 women enrolled in the introductory psychology course at Stanford University.[1] They signed up for an experiment entitled "Effects of Various Activities on Mood" in partial fulfillment of a course requirement. The experiment was run by one female experimenter.

Experimental Task

Most of the more widely used tests of creativity are amenable to showing individual differences that depend on certain specialized skills, such as verbal facility and flexibility or drawing ability. Since the present study attempted to show differences between groups of subjects on the basis of environmental manipulations, it was desirable to find a method of assessing creativity that would minimize individual differences in performance. For the purposes of the present investigation, then, a simple subjective method of assessing creativity was developed, a method that does not depend on specialized skills and yet permits reliable judgments of creativity. In addition, it was desirable, for the purposes of differentiating between creativity and other performance effects, that judgments of creativity be separable from judgments of "goodness" and liking for the products.

A study investigating the adequacy of an art activity for this task was conducted as a pretest. Using colored paper and glue, subjects made collages that were subsequently rated on several artistic dimensions by artist-judges. These judgments, over seven judges, were quite reliable; the interjudge reliability was .77 for creativity ratings and .72 for technical goodness ratings. Moreover, a factor analysis revealed two orthogonal factors, one composed of creativity and related judgments (such as novelty of idea and complexity) and one composed of technical goodness and related judgments (such as organization and neatness). In addition, as desired, judgments of liking and aesthetic appeal loaded weakly on both of these factors. Thus, this collage-making activity fits the criteria proposed earlier: It depends on skills no more specialized than manipulating paper and glue; it permits reliable subjective judgments of creativity and the other artistic dimensions; and judgments of technical competence and aesthetic appeal can be clearly separated from judgments of creativity.

Procedure

After asking the subject to complete a consent form, the experimenter explained that this study was actually a pretest for an experiment to be done the following quarter. This alleged pretest was being run in order to identify activities that would affect most individuals' moods in certain, predictable ways. The subject was told that she would randomly choose one of five different activities, and after engaging in that activity, she would complete a mood questionnaire.

At this point, the experimenter presented five numbered cards to the subject, turned them face down, shuffled them, and asked the subject to choose one. After she had done so, the experimenter consulted a small "activity card" and announced, "Number ____ is . . . the art activity." The experimenter then presented the subject with her materials: one white cardboard, 15 × 20 inches (.38 × .51 m); one small plastic squeeze-bottle of glue; and one large round aluminum tray containing 154 colored pieces of lightweight paper in various shapes and sizes. After presenting the materials, the experimenter asked the subject if she was an artist or had done much collage work. If the subject answered in the affirmative, the session was terminated. (Only three subjects were eliminated on this basis, and they were replaced.) If not, the experimenter went on to introduce the subject's task. In so doing, she stressed that the subject had complete freedom in using the materials to form a design, but that only the materials provided should be used. In addition, the subject was asked to make a design that conveyed a feeling of silliness, "as when a child is acting and feeling silly." This last instruction was given to insure that all subjects would employ the same theme in making their designs, in an effort to reduce extraneous sources of variability.

Following this general introduction, the instructions diverged to produce the eight treatment conditions. (Table 1 summarizes the experimental design.) Assignment of subjects to conditions had been predetermined by a randomized schedule, and up to this point, the experimenter was unaware of the subject's treatment condition. Now, the experimenter turned to the "manipulation" page in the subject's packet and read the crucial instructions. Subjects in the control conditions (nonevaluation – no focus,

---

[1] Males were not used, in an effort to reduce extraneous sources of variability. Pretesting had shown that on this task, females produce artworks that are judged as significantly more creative than those produced by males. The number of subjects was approximately equal in each of the eight conditions: nonevaluation – no focus = 13, nonevaluation – technical focus = 12, nonevaluation – creativity focus = 11, evaluation – technical focus = 11, evaluation – creativity focus = 11, evaluation – specific technical focus = 12, evaluation – specific creativity focus = 12.

Table 1
Experimental Design

Evaluation expectation	Instruction				
	No focus	Technical focus	Specific technical focus	Creativity focus	Specific creativity focus
Absent	C_1	C_2		C_3	
Present	E_1	E_2	E_2	E_3	E_3

Note. The letter in each box indicates whether a condition is control or experimental, and the subscripts link experimental groups to their appropriate controls.

nonevaluation – technical focus, and nonevaluation – creativity focus) were told:

> There is one more important point that I should make before you begin. We won't be using your design as a source of data. We are not interested at all in the activity itself or what you do with the activity. We are *only* interested in the mood you report on the questionnaire. So we do not care about the design itself at all—its only purpose is to provide you with this experience so we can see how it affects your mood.

In addition, subjects in the nonevaluation – technical focus condition were asked to concentrate on the technical aspects of the activity "for this particular mood induction," and subjects in the nonevaluation – creativity focus condition were asked to focus on the creative aspects.

The basic instructions for the five experimental groups (evaluation – no focus, evaluation – technical focus, evaluation – creativity focus, evaluation – specific technical focus, evaluation – specific creativity focus) were:

> There is one more important point that I should make clear before you begin. In addition to your questionnaire, we will be looking at your finished design as an important source of data. We have five graduate artists from the Stanford Art Department working with us, and when this experiment is over, we will have them come in to judge each artwork. They will make a detailed evaluation of your design, noting the good points and criticizing the weaknesses. And since we know that our subjects are interested in how they were evaluated, we will send you a copy of each judge's evaluation of your design in about two weeks.

In addition, subjects in the evaluation – technical focus condition were told that the judges would base their evaluation on how technically good the designs were; subjects in the evaluation – creativity focus condition were told that the judges would base their evaluations on how creative the designs were. Those in the evaluation – specific technical focus condition were told that the judges would make their technical evaluation on the basis of these six elements: (a) the neatness of the design, (b) the balance of the design, (c) the amount of planning evident, (d) the level of organization in the design, (e) the presence of actual recognizable figures or objects in the design, and (f) the degree to which the design expresses something to them. Subjects in the evaluation – specific creativity focus condition were told that the judges would base their creativity evaluation on these seven elements: (a) the novelty of the idea, (b) the novelty shown in use of the materials, (c) the amount of variation in the shapes used, (d) how asymmetrical the design is, (e) the amount of detail in the design, (f) the complexity of the design, and (g) the amount of effort evident. These components were the ones that had, in fact, clustered closely with pretest judges' ratings of technical goodness and creativity, respectively.

After asking the subject if she had any questions, the experimenter looked at the digital clock that had been placed in the room and said, "Okay, it's (time) right now; I'll be back in 15 minutes." She then left the room.

When the 15 minutes had elapsed, the experimenter reentered the experimental room, asked the subject to stop working, and—in keeping with the cover story—presented her with a "Mood Questionnaire." This questionnaire contained 15 mood adjectives and asked the subject to rate herself on each. This was the first of two questionnaires presented to the subject. The second, an "Art Activity Questionnaire," included a number of items designed to assess the subject's interest in and attitude toward the art activity. After completing this questionnaire, the subject was asked a series of questions designed to probe suspicions about the experimental situation, the tasks, or the instructions.[2] The experimenter then fully explained the purposes and hypotheses of the study,

[2] Fifteen subjects, distributed evenly throughout the eight conditions, expressed suspicions about being watched during a 10-minute free-time period that elapsed between administration of the two questionnaires. Since the behavioral measure obtained during that period proved not to be useful, these subjects were retained, and their data appear in all analyses reported here.

noting the subject's reactions and comments. No subject appeared distressed by the deception that had been employed, and all expressed interest in the hypotheses and outcomes of the study.

Dependent Measures

Creativity. The creativity of the designs was the dependent measure of primary interest in this study. Creativity and several other artistic dimensions (including technical goodness) were assessed according to the judging procedure developed during pretesting. Fifteen artists, nine males and six females, served as judges of the designs made by subjects in this study. Each judge had had at least 5 years of experience doing studio art (painting, drawing, or design); most were graduate students enrolled in the Stanford Art Department. These artists were paid for their participation.

The judges worked in individual sessions, rating the 95 designs, which had been affixed to the walls of a lab room. A different random ordering of the designs was used for each judge. Before beginning a judging session, the experimenter gave the judge a brief summary of the general instructions the subjects had received, *without* mentioning the crucial evaluation/nonevaluation instructions or the particular instructions focus that some subjects had received. The judge was shown a sample of the materials that each subject had worked with, as well as a sample of the continuous scale (with 5 reference points marked) on which all ratings would be made.

The judge was told that he or she would judge the 95 designs (always in the same order for a particular judge) on each of 16 different artistic dimensions: (a) expression of meaning, (b) degree of representationalism, (c) silliness, (d) detail, (e) degree of symmetry, (f) planning evident, (g) novelty of the idea, (h) balance, (i) novelty in use of materials, (j) variation of shapes, (k) effort evident, (l) complexity, (m) neatness, (d) overall organization, (o) creativity, and (p) technical goodness. The judge was left alone to do each rating task, which consisted of rating all 95 designs on one of the 16 artistic dimensions. Before rating the designs on any given dimension, the judge was given a brief written definition of that dimension.[3] A different random ordering of the 16 dimensions to be judged was used for each of the 15 judges.

In essence, the rating of the designs can be viewed as a discrimination task for the judges. It was expected that on many dimensions of judgment, the judges would, on the average, see differences between the artworks made by the nonevaluation groups and the artworks made by the evaluation groups. Could the judges, for example, see the artworks of the nonevaluation – no focus group as more creative than those of the evaluation – no focus group? Viewed in this way, the experimental design employed here was a repeated measures design, with judges as "subjects"; for any one artistic dimension, each judge provided data on each of the eight experimental conditions.

Other measures. As noted earlier, a questionnaire designed to assess interest in the art activity was administered to subjects at the end of the experimental session. This questionnaire contained items that, in previous research (Amabile et al., 1976), had served as indicators of intrinsic interest. In addition, an attempt was made to obtain a behavioral measure of interest in the activity. Subjects were left alone in the experimental room for a period of 10 minutes between administration of the Mood Questionnaire and administration of the Art Activity Questionnaire. Some collage-making materials and pieces from a structure-building game had been left on another table in the room, and the amount of time subjects spent playing with these activities during this free time was observed from behind a one-way mirror. It was expected that this behavioral measure would provide results analogous to those obtained on the intrinsic interest questionnaire. The behavioral measure proved not to be useful, however, since few subjects in any condition played with either set of materials during the free-time session.

Results

Preliminary Analyses

Reliability. As a first step in analysis of the creativity results, it was essential to determine that the subjective ratings made by artist-judges were reliable at an acceptable level. Thus, a Spearman–Brown interjudge reliability was calculated for each dimension of judgment (see Nunnally, 1967, p. 233). In general, the reliabilities calculated in this manner were quite high: 12 of the 16 dimension reliabilities were above .80, and the median reliability was .84. Of particular interest is the reliability of the major dependent measure for this study, creativity; this value was quite satisfactory at .79. Only one dimension of judgment, balance, failed to reach an acceptable reliability level; this reliability, at .48, was so much lower than the others that judgments of balance were excluded from further analyses.

These generally high reliabilities bear a special significance, given the nature of the judgment task employed in this study. The

[3] These definitions were all nondirective. For example, the creativity "definition" was, "Using your own, subjective definition of creativity, the degree to which the design is creative."

judges were asked to perform a particularly difficult feat: to work alone in a small room for nearly 3 hours, viewing 95 designs affixed to the walls, making 1,520 separate judgments, and spending barely 5 sec on each one. Given these circumstances, and given particularly that the judges were not trained in any way to agree with one another on this task, their high level of agreement is all the more encouraging.

Factor analysis. A factor analysis (varimax rotation) was performed on the dimensions of judgment to determine if the eight "creativity" dimensions and the seven "technical" dimensions did in fact cluster together.[4] The results of this analysis suggest that the judgments did cluster in this fashion. First, there are clearly two orthogonal factors. Moreover, these were the two primary factors identified in the analysis, and they do indeed seem to be a creativity factor and a technical factor. Seven of the eight original creativity dimensions (creativity, novelty of material use, novelty of idea, effort evident, variation of shapes, detail, and complexity) load high and positive on the creativity factor; all of these loadings are +.80 or higher on that factor and ±.30 or lower on the technical factor. In addition, five of the seven original technical dimensions (organization, neatness, planning evident, balance, and expression of meaning) load high and positive on the technical goodness factor; all of these loadings are +.45 or higher on this factor and ±.16 or lower on the creativity factor.

The results of this analysis differed from those of the pretest in three minor respects. Two component dimensions that had previously loaded high on their respective factors (asymmetry on the creativity factor and representationalism on the technical factor) loaded sufficiently low on those factors here that they were discarded from further analyses. In addition, judges' ratings of "technical goodness" as a single dimension did not, in this study, load any higher on the technical factor than on the creativity factor.[5] Thus, the composite technical goodness measure used in subsequent analyses did not include the single technical goodness dimension of judgment.

Creativity

It was expected that with the exception of the specific creativity instructions group, the artworks produced by subjects who expected evaluation would be judged lower on creativity than the artworks produced by subjects who did not expect evaluation. Judge ratings on creativity and the six creativity component dimensions strongly support this hypothesis.

A composite creativity measure was formed by combining the normalized rating for each of the creativity dimensions: novelty of material use, novelty of idea, effort evident, variation of shapes, detail, and complexity.[6] Means for this composite measure are presented in Table 2.

An overall analysis of variance for the seven groups excluding the specific creativity instructions group (evaluation – specific crea-

---

[4] The factor analysis was done on the average ratings (over all judges) for each of the 95 designs on each of the 16 dimensions.

[5] This result is not surprising, since, in this study, artists' judgments of technical goodness correlated .68 with their creativity judgments. However, it clearly implies that while the technical goodness cluster of judgments on the factor analysis *does* capture the technical aspect of the artworks, the single technical goodness dimension does not. It appears that, unlike the artist-judges in the pretest study, the judges in the present study did not assess simply the *technical* goodness of the designs with their ratings on this one dimension, but an overall Gestalt of "goodness," which included aspects of creativity.

[6] Since the experimental design was treated as a repeated measures design for the creativity and technical goodness measures, with judges as subjects, each subjective measure was analyzed by first obtaining one number for each judge on each of the eight experimental conditions (an average for each condition) and then carrying out repeated measures analyses of variance, dependent t tests, and any additional analyses on these. Thus, for example, the creativity composite scores were formed by first normalizing all judgments on each of the six creativity components and then averaging the normalized ratings for each judge on each component for each condition. Finally, one number was obtained for each judge on each condition by forming a composite of the six components (a simple average). By using this technique of analysis for subjective measures, it is possible to examine overall rated differences between conditions and, at the same time, to account for differential scale usage by allowing each judge to act as his or her own control.

Table 2
Mean Judge Ratings of Creativity

Evaluation expectation	Instruction				
	No focus	Technical focus	Specific technical focus	Creativity focus	Specific creativity focus
Absent	.356	.181		.160	
Present	−.499	−.056	−.466	−.472	.777

Note. These numbers are the means of composites of six normalized components of creativity that clustered on the factor analysis of artist judgments.

tivity focus) was statistically significant, $F(6, 84) = 12.13$, $p < .001$. Thus, a planned contrast was performed on these seven groups to test the hypothesis that control groups (nonevaluation) were judged higher on creativity than experimental groups (evaluation). This contrast was clearly significant, $F(1, 84) = 45.81$, $p < .001$.

This pattern is borne out by a series of paired comparisons between control groups and the relevant experimental groups. As expected, only when evaluation subjects were given specific instructions on how to make a creative design did they produce artworks judged as significantly more creative than those of nonevaluation subjects. The mean rated creativity for this specific instructions group (evaluation – specific creativity focus) is significantly higher than that of the relevant control, $t(14) = -3.88$, $p < .01$;[7] indeed, this group is higher than any other on judged creativity. In all other cases, the nonevaluation groups are significantly higher on judged creativity than the comparable evaluation groups: For the no focus groups (nonevaluation – no focus vs. evaluation – no focus), $t(14) = 9.44$, $p < .001$; for the technical focus groups (nonevaluation – technical focus vs. evaluation – technical focus), $t(14) = 2.07$, $p < .06$; (nonevaluation – technical focus vs. evaluation – specific technical focus), $t(14) = 3.62$, $p < .01$; and for the creativity focus groups (nonevaluation – creativity focus vs. evaluation – creativity focus), $t(14) = 3.79$, $p < .01$.[8]

Technical Goodness

The technical goodness of the artworks—the degree of technical competence displayed by subjects in their work—was chosen as a feature that might be compared with creativity. Means for the composite technical goodness measure (which included organization, neatness, planning, and expression of meaning) are presented in Table 3. As can be seen, for the no focus groups (nonevaluation – no focus and evaluation – no focus) and the creativity focus groups (nonevaluation – creativity focus, evaluation – creativity focus, and evaluation – specific creativity focus), the evaluation groups are rated lower on technical goodness than their nonevaluation controls. Paired comparisons bear out this observation: The nonevaluation – no focus group is rated significantly higher than the evaluation – no focus group, $t(14) = 3.16$, $p < .01$, and the nonevaluation – creativity focus group is rated higher than both the evaluation – creativity focus group, $t(14) = 6.16$, $p < .01$, and the evaluation – specific creativity focus group, $t(14) = 5.00$, $p < .01$. However, this pattern seems to be reversed for the technical focus groups; here, the nonevaluation control (nonevaluation – technical focus) is rated lowest of the three, although it is significantly lower than only the specific technical focus group, $t(14) = -2.21$, $p < .05$.

It appears that at first glance, the pattern of technical goodness results mimics the pat-

[7] All significance tests reported here are two-tailed.

[8] The results from the single creativity measure mirror the results reported for the composite measure in all respects except that the technical focus evaluation groups (evaluation – technical focus and evaluation – specific technical focus) were not different from their control (nonevaluation – technical focus) at acceptable levels of significance.

rn that had been obtained for creativity: ith the exception of the evaluation group hich was told exactly what to do (the spe- fic instructions group in each case), non- aluation groups are rated higher than aluation groups. There is, however, one in- resting deviation from this parallelism. The eativity focus group that was told to expect aluation, but was *not* told specifically what do to receive a good evaluation (evalua- on – creativity focus) was rated very low n creativity (significantly lower than its ntrol, nonevaluation – creativity focus). By ntrast, however, the technical focus group hat was told to expect evaluation, but was ot told specifically what to do to receive a ood evaluation (evaluation – technical fo- us), was *not* rated low on technical good- ess; in fact, it was rated higher (although ot significantly so) than its control group.

Self-Rated Interest

Several items on the Art Activity Question- naire administered to subjects just prior to debriefing were intended to measure their attitude toward the art activity. A composite intrinsic interest measure was formed using six of these items; all six loaded higher than .50 on the intrinsic interest factor obtained in a factor analysis of questionnaire items, and they all correlated significantly with one another. These six items were (a) "Did you view your engagement in the art activity as motivated more by intrinsic factors, like your own interest, or by extrinsic factors, like the experimenter's instructions?" (b) "Was the art activity more like work or more like lei- sure activity?" (c) "How playful did you feel during the activity session?" (d) "How satisfied were you with your performance on the art activity?" (e) "How much do you like your finished design?" and (f) "How much pressure did you feel during the activity session?" This last item loaded high and nega- tive on the intrinsic interest factor, so it was subtracted from the other five in forming the composite.

Means for this composite measure are pre- sented in Table 4. It was expected that over- all, the control groups (nonevaluation) would be higher in self-rated interest than the ex- perimental groups (evaluation). Recall that on the creativity measure, the specific crea- tivity instructions group (evaluation – spe- cific creativity focus) was expected to be an exception to the general pattern. This excep- tion was *not* predicted on the intrinsic interest measure, however. On the contrary, it was ex- pected that even though the specific creativ- ity instructions subjects might exhibit supe- rior creativity in accord with their task in- structions, their intrinsic interest would still be undermined by evaluation expectation.

This overall pattern of results was, in fact, obtained. An analysis of variance on all eight groups yielded a significant overall effect, $F(7, 87) = 2.68$, $p < .025$, and a planned con- trast testing the specific trend of nonevalua- tion groups being higher on intrinsic interest than evaluation groups was statistically sig- nificant, $F(1, 87) = 4.08$, $p < .05$.

In comparison with the creativity results, however, the intrinsic interest results are not as strong. Indeed, only two experimental– control paired comparisons are statistically significant: that for the two no focus groups (nonevaluation – no focus vs. evaluation – no

Table 3
Mean Judge Ratings of Technical Goodness

Evaluation expectation	Instruction				
	No focus	Technical focus	Specific technical focus	Creativity focus	Specific creativity focus
Absent	.254	−.058	.231	.258	−.269
Present	−.081	−.014		−.322	

Note. These numbers are the means of composites of four normalized components of technical goodness that clustered on the factor analysis of artist judgments.

Table 4
Mean Self-Ratings of Intrinsic Interest

Evaluation expectation	Instruction: No focus	Technical focus	Specific technical focus	Creativity focus	Specific creativity focus
Absent	.311	.294		−.059	
Present	−.184	.222	−.568	.207	−.158

Note. These numbers are the means of composites of six normalized measures of intrinsic interest that clustered on the factor analysis of questionnaire items.

focus), $t(22) = 2.07$, $p < .05$, and that for the specific technical focus group and its control (nonevaluation – technical focus vs. evaluation – specific technical focus), $t(22) = 2.77$, $p < .02$.

Despite the failure of specific comparisons, however, the overall planned contrast suggests that it is reasonable to assert that intrinsic interest was undermined by evaluation expectation in this study. This result is particularly important when the two specific instructions groups are considered: Although the technical instructions group (evaluation – specific technical focus) was very high on rated technical goodness, and the creativity instructions group (evaluation – specific creativity focus) was very high on creativity, both of these groups were quite low on intrinsic interest. In other words, as predicted, the specific creativity instructions group (evaluation – specific creativity focus) did *not* exhibit a high level of intrinsic interest to match its high level of creativity.

Discussion

The main hypothesis of the present study—that under nonspecific instructional sets, the expectation of external evaluation will lead to decrements in creativity—was strongly supported by the artist-judges' ratings of creativity. Whether subjects were given no particular focus, a technical focus, or a creativity focus in their instructions, subjects in the evaluation conditions were, overall, rated lower on creativity than subjects in the nonevaluation conditions. In keeping with the theoretical analysis presented earlier, only the specific creativity instructions evaluation group (evaluation – specific creativity focus) was higher than its nonevaluation control on rated creativity. Thus, the present results suggest a reconciliation between the seemingly contradictory findings on the effect of constraint on creativity provided by the overjustification and behavior modification literatures.

Reinterpretation of Previous Findings

The behavior modification studies appeared to demonstrate that creativity can be increased by the offer of rewards for creative performance. This conclusion clearly contradicts the intrinsic motivation view of creativity proposed here: that the imposition of extrinsic constraints (such as rewards or external evaluation) can lead to decrements in creativity. The key to the reconciliation lies in the nature of the task and the nature of the instructions given. In accord with the present thesis, if a creative performance depends on some degree of risk taking and set breaking—some level of production beyond the obvious and commonplace—the imposition of salient extrinsic constraints, establishing an extrinsic motivation, will result in lower levels of creativity. In order to evoke a spontaneously creative performance, a task must have some degree of ambiguity—a nonobvious solution or method of approach. In McGraw's (1978) terms, it must require a *heuristic* rather than an *algorithmic* solution. This was clearly *not* the case in the behavior modification studies cited earlier, and it was not the case in the specific creativity instructions condition in the present study.

The behavior modification studies, for the most part, used verbal tests of creativity. The instructions given to children under reward conditions in those studies effectively eliminated any ambiguity about what constituted a good ("creative") performance; if the experimenters wanted to demonstrate that "fluency" was under experimental control, they told the children that they would be rewarded for producing a large number of ideas. Not at all remarkably, children produced large numbers of ideas under these conditions. And, apparently, the instructions given to the specific creativity instructions group in the present study also succeeded in reducing the ambiguity in the task; subjects were told to come up with a novel idea, to use the materials in a novel way, to make a detailed and complex design, and so on. Since, as was evident from pretest results, judges considered complex, detailed designs with novel ideas and novel use of materials to be creative, this group achieved very high creativity scores. What is crucial here is that, within the same experimental design, when subjects were given evaluation instructions but *not* told specifically what to do, their creativity was dramatically lower. And, when subjects did *not* expect evaluation, their creativity remained high—no matter what they were asked to focus on.

The present thesis proposes motivational state as a mediator of the observed performance effects. The results obtained on subjects' intrinsic motivation, while generally supportive of this proposition, are not as strong as might have been desired. An attempt at obtaining a behavioral measure of intrinsic interest failed because of the generally low level of any behavior emitted by subjects during the free-time period. The self-rating questionnaire on intrinsic interest did show significant interest differences consistent with the hypothesis. However, because some specific paired comparisons between experimental and control groups did not yield the predicted significant differences, further research is required before the observed creativity decrement can reliably be attributed to decrements in intrinsic motivation.

Practical Implications

In determining the practical implications of the present results, it is perhaps most instructive to consider the two no focus groups (nonevaluation – no focus and evaluation – no focus). These groups permit a test of the basic, uncluttered version of the hypothesis: Evaluation group subjects will be less creative than nonevaluation group subjects and will show less intrinsic interest. These two groups provide an analogue to conditions that exist in many social settings; in classrooms, for example, children are often given art projects and writing projects that will be graded, but the criteria for evaluation are left unspecified. Appropriately, these two groups provide the clearest, most consistent pattern of results obtained in this study: The nonevaluation group was significantly higher on rated creativity and technical goodness and significantly higher on self-rated intrinsic interest. In fact, with the exception of the specific creativity instructions group, the no focus nonevaluation group was higher than any other on rated creativity; moreover, it was the highest of all eight groups on self-rated intrinsic interest and second highest on rated technical goodness. In all respects, then, the nonevaluation group here performed better than the evaluation group and felt, apparently, more intrinsically motivated.

The specific creativity instructions group (evaluation – specific creativity focus) is of particular interest when considering practical applications of this work, since this group was higher in rated creativity than any other. Indeed, this result might seem to suggest that there is no reason *not* to use an extrinsic constraint, if it is accompanied by specific performance instructions. It can be argued, however, that there are several flaws in this approach. First, for most activities, it is difficult or impossible to specify the behaviors that would lead to a creative performance. Second, the high creativity of subjects in the specific creativity instructions group was *not* accompanied by a high level of technical competence; in fact, the rated technical competence of this group was significantly lower than control. Finally, and perhaps most

importantly, the high creativity of this group was not accompanied by a high level of intrinsic interest.

It is important to note that the present analysis and the present study deal with relatively low, "nonprofessional" levels of creativity. While we might expect that some professional scientists or artists could succumb to the overjustification effect, it seems eminently clear that many highly creative people go on being creative in the face of numerous extrinsic constraints. (See Simonton, 1977, for a historical look at this question.) There are two possible explanations for the seeming impotency of the overjustification effect at this level. First, it is probably the case that these exceptional individuals have largely internalized the norms and standards by which their work would be judged. Thus, external evaluation becomes less salient and less necessary. Second, highly creative and successful individuals almost certainly have a very high level of intrinsic interest in their work, and they are probably well aware of this interest. The overjustification effect is proposed to occur only when internal states are ambiguous or nonsalient (see Bem, 1972).

The practical implications of these results are perhaps most relevant for educational settings. They suggest that if creativity is to be fostered and interest maintained, care must be taken in the use of control in the classroom. Surely, some children would have no interest in even attempting a task—say, an art activity—unless some control were exerted over their behavior. But the present results suggest that if control is *over*sufficient, undesirable consequences could result. Consider what the state of modern physics might be if Einstein had not been clever enough early in his career to circumvent the detrimental effects of external evaluation.

Corrections to Lynch and Cohen

In the article, "The Use of Subjective Expected Utility Theory as an Aid to Understanding Variables That Influence Helping Behavior," by John G. Lynch, Jr., and Jerry L. Cohen (*Journal of Personality and Social Psychology*, Vol. 36, No. 10, pp. 1138–1151), the following corrections should be made:

1. The last two lines of Table 1 (p. 1140) should read

$SEU_{not\ help} = \sum_{i=3}^{4} P_i U_i$	−5.4	−2.5	−.4
$SEU_{help} - SEU_{not\ help}$	6.4	2.5	−.6

2. The symbols used in the curves in the left and right panels of Figure 1 (p. 1143) are not related to the manipulated levels of probability in the manner specified in the legends of these panels. Therefore, the symbols in the legends should be ignored. In both legends, probability levels are listed in ascending order of subjective magnitude, and the higher the level of probability, the steeper the slope of the curve to which it properly corresponds.

3. The third sentence in the first full paragraph on page 1146 should read, "The Probability 1 × Utility 1 × Probability 2, Probability 1 × Utility 1 × Utility 2, Probability 1 × Probability 2 × Utility 2, and Utility 1 × Probability 2 × Utility 2 interactions were all significant, with $F(8, 26) = 5.22$, 9.52, 3.89, and 4.61, respectively ($p < .001$)."

Research suggests that kinesthetic aftereffect (KAE) scores reflect status on a postulated stimulus intensity modulation (SIM) mechanism that damps down subjective stimulus intensity for some (reducing) and increases it for others (augmenting). Such a mechanism would help account for empirically observed individual differences in such behaviors as pain tolerance, sensory deprivation reactivity, and stimulation seeking. It was hypothesized and confirmed in three adult female samples that KAE varies curvilinearly over the menstrual cycle: Greater KAE reduction occurs at the cycle's beginning and end. Neither tiredness, oral contraception, medication, attention, nor social expectations can explain this finding. Of the behaviors studied in the KAE literature, only five are also encompassed by the menstrual cycle literature. Four of these (antisocial behavior, acute schizophrenic episodes, accidents, and activity level) show similar curvilinearity over the cycle. We hypothesize that cyclical variation in the SIM mechanism mediates the curvilinear pattern observed for both these four behaviors and KAE.

This study explores the relationship between menstrual cycle and kinesthetic aftereffect (KAE). Prior findings support the hypothesis that KAE scores reflect individual differences in a postulated mechanism that modulates the subjective intensity of incoming stimulation. If KAE scores vary over the menstrual cycle, then the stimulus intensity modulation (SIM) mechanism may similarly vary over the cycle, providing a useful framework for understanding certain reported behavioral variations across the cycle.

A brief report of this research was presented at the meeting of the American Psychological Association, New Orleans, September 1974. We thank Kathleen McGraw, Patricia Renner, and Valerie Finkelstein for serving as experimenters in these studies and Roy Freedle, Donald Goodenough, Leland Van den Daele, Laraine Schwartz, and Ruth Sharabany for their critical comments of an earlier draft of this aritcle.

Requests for reprints should be sent to A. Harvey Baker, Department of Psychology, Queens College, City University of New York, Flushing, New York 11367.

Kinesthetic Aftereffect as an Index of Stimulus Intensity Modulation

Several researchers (e.g., Baker, Mishara, Kostin, & Parker, 1976; Mishara & Baker, 1974; Petrie, 1967; Silverman, 1967) have hypothesized that the central nervous system functions as if it had a modulator mechanism, which differs from person to person. This mechanism acts like a volume control, modulating the subjective intensity of incoming stimulation. For people with the volume control "set low" ("reducers"), the subjective intensity of incoming stimulation is presumably attenuated. Under normal circumstances, reducers are stimulus deprived and seek more stimulation to compensate. Although they can handle high-intensity stimulation well, they are very uncomfortable when environmental stimulation is low, as in sensory deprivation

Copyright 1979 by the American Psychological Association, Inc. 0022-3514/79/3702-0234$00.75

situations. In contrast, people with the volume control "set high" ("augmenters") are subjectively overloaded with stimulation, show stimulation-avoidant behaviors, and cope well with situations involving minimal intensity.

Procedures used to measure this postulated mechanism include average evoked response to stimuli of varying intensities (e.g., Lukas & Siegel, 1977; Silverman, Buchsbaum, & Henkin, 1969); indexes of Russian "strength of the nervous system" (Sales, Guydosh, & Iacona, 1974; Sales & Throop, 1972); electrodermal response (Depue & Fowles, 1976); the R–A Scale, a self-report questionnaire regarding preferred degree of stimulus intensity (Vando, 1974); a self-report index assessing a wide range of behaviors and attitudes (Baker et al., 1976); and KAE (e.g., Buchsbaum & Silverman, 1968; Deaux, 1976; Petrie, 1967; Schooler & Silverman, 1969).

KAE has been the most widely used and has been related to three other SIM indexes (see text below). KAE involves changes from pretest to test trials in width judgments of a standard block that occur with intervening rubbing of an aftereffect-inducing block different in width from the standard block. Two major KAE variants exist. In the one-hand variant (Petrie, 1967), the subject rubs the inducing block with one hand while resting the other. There is a two-hand variant (e.g., Buchsbaum & Silverman, 1968); however, it has been less frequently used in KAE/SIM validity studies than the one-hand version, and it may not tap the same psychological process (Schooler & Silverman, 1969). We therefore treat only the one-hand variant here.

When, as in this study, the aftereffect-inducing block for one-hand KAE is larger than the standard block, judged width of the test block decreases on the average following aftereffect induction (e.g., Bakan & Thompson, 1965). Reducers' width judgments decrease the most following aftereffect induction, and augmenters' decrease the least (or even increase) (Mishara, Baker, Parker, & Kostin, 1973).

Consistent with the SIM hypothesis, reducing scores on KAE are associated with (a) greater pain tolerance (Petrie, Collins, & Solomon, 1958; Poser, 1960; Ryan & Foster, 1967; Sweeney, 1966); (b) lesser sensory-deprivation endurance (Petrie et al., 1958, Study 2); (c) higher "need for stimulation" (Mishara & Baker, 1974; Ryan & Foster, 1967; Sales, 1971, 1972); (d) delinquency (Compton, 1967; Petrie, McCulloch, & Kazdin, 1962); (e) more accidents (Petrie, 1967, p. 25); (f) schizophrenia (Petrie, Holland, & Wolk, 1963); (g) greater activity level (Petrie, 1967, p. 100; Sales, 1971); and (h) use of amphetamines rather than barbiturates (Deaux, 1976). Regarding other indexes of SIM status, KAE reducing scores are associated with (i) reducing, as assessed by average evoked response (Schooler, Buchsbaum, & Carpenter, 1976); (j) higher sensory thresholds (as well as with two other indexes of a "strong" nervous system) (Sales & Throop, 1972); and (k) higher scores on a self-report index (Baker et al., 1976).

Despite these validity findings, critics have recently contended that KAE lacked retest reliability (e.g., McDonald, 1974; Morgan & Hilgard, 1972; Platt, Holtzman, & Larson, 1971), showed intermittent validity (e.g., Sales & Throop, 1972; Weintraub, Green, & Herzog, 1973), and thus should not be used as a personality index. However, we (Baker et al., 1976; Baker, Mishara, Parker, & Kostin, 1978; Mishara & Baker, 1974) and others (Bakan & Thompson, 1962) have demonstrated that systematic individual differences in practice effects bias second-session KAE scores. Low retest reliability, which is caused by such practice effects, can be disregarded. When KAE–personality findings are restricted to one-session studies, there is clear evidence of validity (Baker et al., 1976). Internal consistency, the appropriate reliability statistic for a one-session task, is high in 10 samples (Mishara & Baker, 1978). We conclude that the KAE–SIM formulation shows good construct validity when a one-session design is used.

Kinesthetic Aftereffect and the Menstrual Cycle

SIM is presumed to reflect not only stable individual differences (trait) but also tran-

sient organismic fluctuations (state) (Petrie, 1960; Petrie et al., 1963). If KAE is a sensitive index of current modulator status, it should reflect both between-people differences in trait, as the validity findings reviewed above indicate, and transient changes in state. The latter possibility is supported by Gupta's (1974) finding that state-altering variables such as Dexedrine and phenobarbital significantly affect KAE performance.

The present KAE–menstrual cycle hypothesis is based on two interrelated assumptions: (a) Strong stimulation (whether external or internal) is presumed to lead to a shift toward reducing on the part of the SIM mechanism.[1] This shift results in a damping down of the subjective intensity of incoming stimulation (cf. Petrie, 1967, pp. 51–60). The KAE scores should reflect this shift toward reducing. (b) One important form of internal stimulation, pain (e.g., lower abdominal cramps, tender breasts) is presumed to vary curvilinearly over the menstrual cycle, with maximal pain occurring at the cycle's beginning and end (Dalton, 1964; Moos et al., 1969).[2] If these two assumptions are correct, then (a) there should be a shift toward SIM reduction at the menstrual cycle's beginning and end, when pain is maximal, and (b) KAE scores should index this shift in SIM. Where, as here, the aftereffect-inducing block is larger than the test block, we hypothesize greater KAE reduction (larger aftereffect) at the beginning and end of the menstrual cycle—in other words, we hypothesize a curvilinear relationship between KAE and locus in the menstrual cycle.[3]

Relationship of This Study to the Menstrual Cycle Literature

Very few of the reported menstrual cycle findings have withstood recent critical reviews (O'Connor, Shelly, & Stern, 1974; Parlee, 1973, 1974; Redgrove, 1971; Sommer, 1973; Zimmerman & Parlee, 1973). Improper generalizations from sample to population, problems in drawing causal inferences from correlational data, inadequate statistical treatment, and failures in replicating earlier findings are some central problems raised by the critics.

The reviews generally agree that a few consistent, replicable findings of periodicity have been reported regarding (a) self-reported symptoms such as mood changes (Coppen & Kessel, 1963; Moos et al., 1969), (b) incidence of criminal behavior (Dalton, 1961; Morton, Additon, Addison, Hunt, & Sullivan, 1953), and (c) incidence of psychiatric crises (Dalton, 1959; Glass, Heninger, Lansky, & Talan, 1971; Jacobs & Charles, 1970). As Parlee (1974) and Sommer (1973) note, few replicated findings exist involving objectively measured nonverbal behaviors such as performance on cognitive tasks, reaction time, and athletic performance. Parlee (1974) and Sommer (1973) conclude that (a) most of the replicable findings are in behavioral areas that can be influenced by social–cultural expectations concerning how women "should" behave or feel at different phases of the cycle and that (b) few, if any, consistent and significant findings exist in areas where no clear cultural expectations exist. They hold, in effect, that most psychological and behavioral changes reported do not reflect phenomena intrinsically associated with the cycle (such as hormonal or other physiological changes) but rather are "artifactual," arising from social–cultural expectations.

Recently, a few carefully done studies have focused on objective, nonverbal behaviors—

---

[1] This assumption is supported by findings that (a) high-intensity auditory stimulation by itself increases pain tolerance (Gardner & Licklider, 1959), and high-intensity auditory stimulation combined with suggestion also increases pain tolerance (Melzack, Weisz, & Sprague, 1963) and decreases self-reported pain (Lavine, Buchsbaum, & Poncy, 1976); that (b) pain tolerance also increases with nonpainful somatosensory stimulation (Higgins, Tursky, & Schwartz, 1971; Satran & Goldstein, 1973); and that (c) the strong internal stimulation of organic pain raises the pain threshold (decreases pain sensitivity) in undamaged areas of the body (Hazouri & Mueller, 1950; Mersky & Evans, 1975).

[2] Our assumption here is that these changes in self-report of pain over the menstrual cycle are primarily due to hormonal and other physiological changes over the cycle, a view consistent with Dalton (1964) and Lennane and Lennane (1973), among others. We are aware that some would argue (e.g., Parlee, 1974) that such findings reflect social expectancy effects, an alternative hypothesis that will be considered briefly in the discussion section.

[3] Petrie (1967, p. 103) mentions, without presenting any supportive data, pilot findings consistent with our prediction regarding premenses.

not likely to be mediated by social expectations. For example, both conditionability to an aversive stimulus (Asso & Beech, 1975) and rod-and-frame test performance (Klaiber, Broverman, Vogel, & Kobayashi, 1974) vary over the menstrual cycle. More such studies must be done before the significance of these findings can be determined. Here, we attempt to relate another objectively measured, nonverbal behavior to the menstrual cycle.

Method

Apparatus

Following Petrie (1967), apparatus included a 30-inch (76.20 cm) long tapered comparison wedge, a 2.5-inch (6.35 cm) wide aftereffect induction block, and a test block (whose width is specified below for each sample). A mounted ruler ran the length of the comparison wedge. Around the ruler were a pair of finger guides, allowing the exact location of the subject's hand on the wedge to be recorded at the end of each trial. The subject was blindfolded and seated in front of a table that had the apparatus on it.

Subjects

Three independent groups of right-handed women ($ns = 47$, 14, 55), predominantly of college age ($Ms = 20.5$, 20.6, and 20.9 years, respectively), were tested. The samples are reported separately because of minor procedural differences: Samples 1 and 2 were tested concurrently by two female experimenters using different-sized KAE test blocks—2 inches (5.08 cm) and 1.5 inches (3.81 cm), respectively. Sample 3 was run 1 year later by a different female experimenter with the 1.5-inch (3.81 cm) wide test block. Three comparison samples of right-handed males ($ns = 31$, 10, and 59; mean ages = 19.6, 21.1, and 21.2 years, respectively) were run concurrently with the three female samples.

Procedure

Because of the differential bias in repeated KAE administrations discussed above, the more ideal procedure of using multiple KAE administrations over the menstrual cycle's course was contraindicated. An 18-trial KAE procedure was thus given *once* to each subject, following Petrie's (1967) detailed procedures exactly. The most important features of Petrie's standardized procedure include the following: (a) On each of the 18 judgments, subjects held the test block with the thumb and forefinger of the right hand and indicated its width on the tapered block with the thumb and forefinger of the left hand. (b) There were two practice trials, four pretest trials, and then three aftereffect-induction periods (90, 90, and 120 sec long, respectively), each followed by four test judgments (12 test trials in all). (c) Before KAE, subjects rested their hands for 45 min so that nothing touched their thumbs and forefingers (cf. Petrie, 1967, pp. 107–127 for further details).

Scores

The KAE score was the mean of the 12 test judgments minus the mean of the four pretest judgments. Negative scores represent the usual aftereffect (width judgments on test trials smaller than on pretest trials). The most negative scores (largest aftereffect) indicate reducing; minimally negative—or even positive—scores (smallest aftereffect) represent augmenting.

Interview

As part of a large questionnaire battery orally administered by the experimenter during the 45-min rest period, the subject estimated onset date of next menses. Based on this estimate, *raw* menstrual cycle score (number of days before onset of menses) was calculated.

In Sample 3, a more refined procedure—occasionally used in recent menstrual cycle studies (e.g., Golub, 1976)—was adopted: Cycle length (date of most recent onset and date of onset of next menses) was estimated at the time of the KAE administration, and then the actual date of onset of the next menses was verified by follow-up phone calls.[4] This permitted, for Sample 3 only, conversion of the raw menstrual cycle score into an adjusted menstrual cycle score[5] based on a standard 29-day cycle.[6]

Information on possible confounding variables was also collected: (a) rating of tiredness now as com-

---

[4] The validity of subjects' estimates can be assessed (a) by correlating number of days until next onset, based on estimated versus confirmed onset dates, or (b) by computing the mean absolute difference between estimated and confirmed dates. In Sample 3 and in a larger follow-up study regarding menstrual cycle estimates, the validity correlations were high ($rs \geq .92$) and the absolute differences adequately small (1.0 and 2.1 days for Sample 3 and the follow-up sample, respectively).

[5] For example, suppose a particular subject had a cycle length of 24 days and that she was administered KAE on the 6th day before onset of next menses. The day on which she was tested was first converted into a percent of her cycle, in this case 25%, and then the percent was reconverted to days based on the standard 29-day cycle, in this case to 7.25 days. Employment of a standard cycle is a more refined procedure that has occasionally been used in the menstrual cycle literature (e.g., Moos et al., 1969).

[6] The decision to specify the standard cycle as 29 days is based on the mean cycle length found in a large study ($n = 2{,}542$) by Sheldrake and Cormack (1976) and on the median mean cycle length determined from a review of 21 other studies (Presser, 1974).

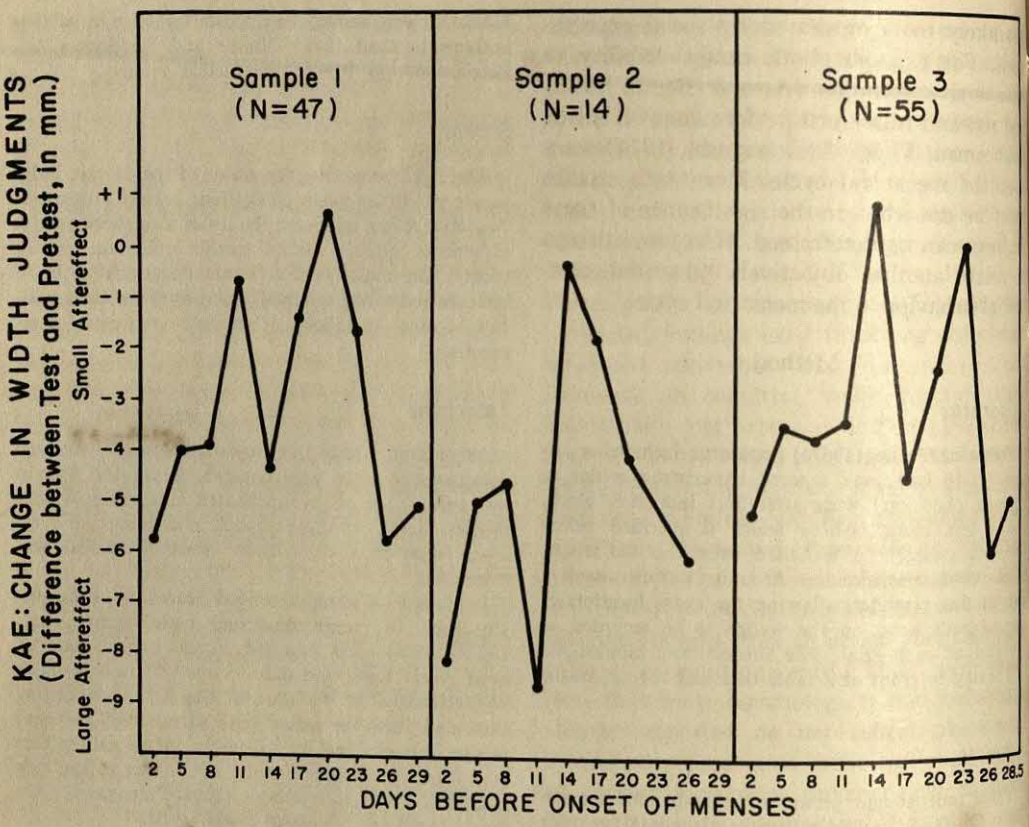

Figure 1. Menstrual cycle affects kinesthetic aftereffect (KAE).

pared to usually (on a 7-point scale); (b) oral contraceptive usage; and (c) any kind of medication or drug usage during the past 12 hours.

Since the same experimenters conducted the interviews and administered the KAE task, the experimenters were not told the purposes and hypothesis of the study.

Results

Figure 1 presents the KAE scores for each sample as a function of days before onset of next menses. To smooth the curves, reported day of the cycle was collapsed into 10 equal intervals of 3 days each. For Sample 2, no subjects fell in two of these intervals, so only 8 data points are depicted. For Sample 3, the last interval consists of 2 days only—Days 28 and 29 of a standard 29-day cycle (see Method section).

These curves each show irregularity—most notably, a dip near midcycle (an issue treated briefly in Footnote 11). Despite this irregularity, the curves generally show the predicted curvilinear pattern.

Test of the Main Hypothesis

Correlational analysis. One way to test for curvilinearity is to ascertain the degree to which the observed data can be fitted by a curve that looks like an inverted U, with (a) the most negative scores (largest aftereffect) at the beginning and end of the cycle, (b) the least negative scores (smallest aftereffect) at the middle, and (c) days equidistant from the midpoint having the same value.

The choice of method to test for curvilinearity was shaped by the size of the present samples, the goal of treating menstrual cycle as a continuous variable (many studies have broken up the cycle into "phases," the definition of which differs from study to study), and the goal of using all information available. The following procedure met these con-

straints: First, the raw menstrual cycle score (i.e., subject's estimate) was transformed into the absolute value of each day's deviation from midcycle (Day 15).[7] This procedure folds one arm of the predicted inverted U-shaped curve onto the other arm (days with identical predicted KAE, for example, 1 and 29, have the same value). Since we expected a curve, we then squared these deviations from Day 15 to produce our transformed menstrual cycle score. According to the curvilinear hypothesis, (a) the least negative KAE scores (augmentation) occur at midcycle, where the smallest values of the transformed scores occur (e.g., raw menstrual cycle score of Day 15 corresponds to a value of 0^2 on the transformed scale); and (b) the most negative KAE scores (reduction) occur at both ends of the cycle, where the largest values of the transformed scale occur (for example, raw scores of 1 and 29 both correspond to a transformed value of 14^2). Thus, a negative linear relationship should obtain between KAE and the transformed scores.

For Samples 1, 2, and 3, the Pearson product-moment correlations between KAE and the transformed menstrual cycle scores were $-.237$ ($p \approx .05$), $-.602$ ($p < .05$), and $-.245$ ($p < .05$), respectively.[8] The average correlation (McNemar, 1969) was $-.285$ ($p < .002$). Since the main hypothesis involved a directional prediction, p values are for one-tailed tests.

Two double checks on the correlational analysis. These correlations approximate one-way analysis of variance with menstrual cycle as the independent variable (with 29 levels) and with curvilinearity tested by quadratic trend analysis. Because sample size was far too small, one-way analyses of variance using trend analyses could only be employed with far fewer than 29 menstrual cycle levels. The raw menstrual cycle scores were here collapsed into 10 levels for Samples 1 and 3 (see Figure 1) and into 4 levels for Sample 2. Resulting Fs from the quadratic trend analyses (dfs = 1, 44; 1, 10; 1, 52) were 2.90, 4.59, and 3.68, respectively. Combining probabilities for independent tests on the same hypothesis (Winer, 1962), $\chi^2 = 19.40$, $p < .01$.

For the second double check, the three samples were pooled, and subjects were classified into two categories occasionally used (e.g., Dalton, 1964) in menstrual cycle studies: (a) paramenstruum (week before and days of menses)[9, 10] versus (b) midcycle (the rest of the cycle). Paramenstruum females ($M = -4.92$ mm, $SD = 4.08$ mm) showed greater KAE reducing, $t(114) = 3.18$, $p < .001$, than midcycle females ($M = -2.34$ mm, $SD = 4.35$ mm). Since this single simple analysis has the advantage of providing a large n for each cell, certain of the later analyses of secondary issues are patterned on it.

Some Secondary Issues

Male–female comparisons. Although few menstrual cycle researchers (e.g., Dalton, 1964) have used comparison groups of males, Parlee (1973) recently enunciated a rationale for employing this admittedly not perfect control procedure: She asserts that the use of nonmenstruating individuals (for example, males) can help in both description and understanding by providing a baseline with which to compare behaviors associated with different parts of the menstrual cycle.

Paramenstruum females showed greater reduction (larger aftereffect) than males in

---

[7] Day 15 is the day exactly in the middle of the standard 29-day cycle used here.

[8] When the day of menstrual cycle raw score is converted into an adjusted score for a standard 29-day cycle, which was possible only for Sample 3, the value of the correlation becomes slightly higher, $r = -.258$.

[9] For menstruating subjects, days of menses at time of KAE testing ranged from Day 1 to Day 5 of menstrual flow.

[10] Because our hypothesis was based, in part, on cyclical variation of painful symptoms, we used the same cutoff points as Moos (1968), whose extensive ($n = 839$) study found that more women complain of painful symptoms during menstruation and during *the week* before menses relative to intermenses. When we review other menstrual cycle studies, we use the term "paramenstruum" to refer to findings clearly associated with the cycle's beginning and end either as defined by Dalton (1964; that is, the 4 days before and the 4 days after menses) or as defined by us or including slight variations on this definition (e.g., 1 week before menses and 1 week after menses, as used by Glass et al., 1971).

each sample. For paramenstruum females, Ms = −4.97, −5.26, and −4.86 mm (SDs = 4.97, 1.97, and 3.60 mm; ns = 16, 5, and 19) for Samples 1–3, respectively. For males, Ms = −1.98, −1.95, and −3.45 mm (SDs = 5.75, 2.38, and 2.99 mm; ns = 31, 10, and 59). Comparisons of paramenstruum female and male KAE scores within each sample gave t values (dfs = 45, 13, and 76) of 1.76, 2.69, 1.57; $p < .10$, $p < .02$, and $p < .14$, respectively. Combining probabilities across samples (Winer, 1962), $\chi^2 = 16.36$, $p < .02$. (All p values are for two-tailed tests, since there was no a priori directional hypothesis here.)

Midcycle females in Samples 1 and 2 (Ms = −2.37 and −2.85 mm; SDs = 5.07 and 3.86 mm; ns = 31 and 9, respectively) also showed greater reduction (*larger* aftereffects) than the corresponding males (see above), but this difference was clearly not significant, ts(60) and (17) = .28 and .63, *ns*. In Sample 3, midcycle females ($M = -2.19$ mm; $SD = 3.60$ mm; $n = 36$) showed less reduction (smaller aftereffect) than the corresponding males. This difference, opposite in direction to the nonsignificant male–female differences for Samples 1 and 2, approached the conventional level of significance, $t(93) = 1.67$, $p < .10$. Taken together, these data suggest that there is no difference between males and midcycle females on KAE.[11]

Given that paramenstruum females do, but midcycle females do not, differ from males, one may ask whether females in general differ from males. For all females pooled, KAE scores are −3.24, −3.71, and −3.06 mm (SDs = 5.13, 3.43, and 3.75; ns = 47, 14, and 55) for Samples 1–3, respectively. (See preceding text for corresponding male values.) Male–female comparisons within each sample gave t values (dfs = 76, 22, and 112) of .97, 1.42, and .61, respectively, *ns*. In Samples 1 and 2, females show greater reduction (larger aftereffect); in Sample 3, they show lesser reduction (smaller aftereffect). Overall there is no evidence of a significant sex difference when all females are involved in the comparison. This finding is consonant with reports from three earlier, single-session studies employing the same one-hand KAE procedure used here (Barthol, 1958; Charles & Duncan, 1959; Spitz & Lipman, 1961).

Possible confounding variables. We analyzed three variables that might have confounded the observed menstrual cycle–KAE relationship: (a) tiredness, which reportedly fluctuates over the cycle (Dalton, 1964); (b) oral contraceptive use, which affects mood and behavior (Kutner, Phillips, & Haag, 1971); and (c) use of drugs or medication, which might vary systematically over the cycle, and which can affect KAE (Gupta, 1974). Each variable was assessed by self-report. Two separate 2 × 2 unweighted-means, independent group analyses of variance were undertaken on the KAE scores with (a) menstrual status (paramenstruum vs. midcycle) as one variable and (b) degree of tiredness (more tired than usual vs. the same or less tired than usual) and oral contraceptive status (use vs. not use), respectively, as the other variable. No significant interaction was observed between degrees of tiredness and menstrual status, $F(1, 112) = .06$, *ns*, or between oral contraceptive status

[11] Perhaps a true male/midcycle female difference exists that is obscured by the presence of the dip that each sample's curve displays somewhere in the middle of the cycle (see Figure 1). Since our hypothesis is based in part on findings of variation in painful symptoms over the cycle, it is relevant to note here that in addition to the more common report of painful symptoms at the beginning and end of the cycle, some women also report experiencing pain in the middle of the cycle, about the time of ovulation. Indeed, Vollman (1974) regards such midcycle pain as one test of time of ovulation, noting that for some women this pain is so severe as to be incapacitating. Moos et al. (1969) plotted reports of painful symptoms and found maximal values at either end of the cycle and also an increase in self-reported pain in the middle of the cycle. In this context, the increase in reduction on KAE in the middle of the curves for our three samples is consistent with the assumption that an increase in internal pain leads to damping down (reduction) on the part of the postulated modulator mechanism. Exploratory t tests were undertaken in Sample 3, where the most precise menstrual cycle measurement was made. These indicate that the mean of Days 16–18 (depicted as Day 17 on the graph) differed from both the mean of Days 22–24, $t(11) = 2.98$, $p < .02$, two-tailed test, and from the mean of Days 13–15, $t(91) = 2.41$, $p < .05$. This exploratory "finding" of a midcycle dip warrants further investigation.

and menstrual status, $F(1, 98) = .07$, *ns*. (The latter *n* is smaller here because the experimenter inadvertently forgot to inquire about oral contraceptive status for some subjects.)

Finally, we assessed whether the KAE–menstrual cycle finding might artifactually reflect differential use of drugs and medication over the cycle. If, for example, drugs and medications that lead to greater reducing (Gupta, 1974) were used more at paramenstruum and drugs that lead to greater augmentation were used more during midcycle, such differential drug use might have produced our finding. To see if the findings would hold, independent of drug usage, we simply dropped all subjects who reported using drugs and/or medication in the 12 hours before testing and computed a *t* test between the remaining midcycle and paramenstruum females. There was still a menstrual cycle–KAE effect, $t(89) = 2.66$, $p < .005$.

Discussion

Observed Kinesthetic Aftereffect/Menstrual Cycle Relationship

Effect magnitude. In three samples, KAE scores show the same curvilinear pattern over the menstrual cycle. How large is this effect? Effect magnitude can be assessed from two perspectives—means (effect size) or variability (explained variance): (a) Using Cohen's (1969) *d* statistic, paramenstruum and midcycle females differ in KAE means by .52, .79, and .74 *SD* for Samples 1–3, respectively. Cohen described effects of this size as "medium" (Sample 1) and "large" (Samples 2 and 3). However, (b) the average correlation of .285 shows that menstrual cycle explains 8% of the variance in KAE scores, a significant but modest amount. We suspect that improved methodology and specification of the midcycle dip would strengthen the correlational results (see Footnote 11).

Possible confounding variables. Elimination of possible confounding variables strengthens the findings. Empirical analyses show that tiredness, oral contraceptive use, and the effects of drugs and/or medication do not account for the results. On logical grounds, one can eliminate a possible attentional hypothesis: If cyclical variation in pain and discomfort (Moos et al., 1969) directly affects attention, then attention to the KAE task would presumably be lower at menses and premenses. Since KAE is minimal with lessened attention (Bakan & Thompson, 1965), one might predict *greater* KAE at midcycle, whereas smaller aftereffects were found here.

Social expectancy effects. It appears that the KAE findings cannot be explained in either of the two primary ways in which social expectancy effects have been invoked to account for certain prior menstrual cycle findings (Parlee, 1974; Sommer, 1973): (a) When interpreting a correlational relationship between the menstrual cycle and some other variable, the *researcher* may, because of his or her social expectations, ascribe causal status to the menstrual cycle when it is an effect. For example, Dalton (1964) interpreted the greater frequency of accidents at paramenstruum as being caused by psychological processes associated with the menstrual cycle and ignored the alternative hypothesis (Parlee, 1973) that stress associated with the accident accelerated menses' onset, thus leading to this "finding." We can see no way in which taking KAE might have any such effect on menstrual cycle locus. (b) The *subject*, because of her social expectations, may behave differently at or near menses—for example, doing more poorly on a task because she believes women do poorly then. KAE, however, is not a "right or wrong" task that focuses on simple performance errors. Nor do we know of any social expectancies about when augmenting rather than reducing errors occur on KAE. So, neither type of social expectancy effect is likely to occur here.

The method of this study. Precise physiological assessment (assay of blood samples, assessment of basal temperature, and indexes of major metabolites in the urine) of the menstrual cycle variable is important for accurate measurement, since pronounced individual differences exist in occurrence of ovulation and in patterning of hormonal secretions. But these procedures are quite expensive and

difficult. An admittedly simpler and more economical approach seems appropriate when first exploring a given domain for possible menstrual cycle relationships. In a situation in which social expectancies have an effect, use of self-report measures might well increase the role of such expectations, and thus Type I errors would be more likely. With such biasing effects ruled out, the decrease in accuracy in menstrual cycle assessment due to self-reports should simply make verification of a directional hypothesis such as ours more difficult. Studies using more precise menstrual cycle measurement procedures should simply find a stronger effect.

Implications for KAE methodology. Is it feasible to continue to use KAE as a measure of trait since we and Gupta (1974) have shown that state variables affect KAE? Yes. Only 2 (Deaux, 1976; Schooler et al., 1976) of the 18 KAE validity studies cited in the introduction controlled for state. Thus, state need not be controlled to obtain significant personality findings with KAE. Of course, a useful task for improving KAE's predictive power would be the development of some means of separating state and trait variance.

Possible Behavioral Implications

In contrast to most menstrual cycle studies, we observed a relationship that (a) holds across independent samples, (b) involves objective measurement on a laboratory-type task, and (c) cannot be explained by social expectancy or (d) by other obvious sources of confounding. What are the possible behavioral implications of this finding?

According to KAE validity studies, between-people differences in KAE scores (trait) correlate with between-people differences in diverse psychological domains. Based on our present findings for females, is what appears to be a within-person cyclical variation in KAE scores (state) similarly associated with a within-person cyclical variation in some or all of these same psychological domains?

Our literature review shows that five of these domains have been studied in relation to the menstrual cycle. For these five, the KAE validity literature indicates that KAE reducing scores are associated with delinquent behavior, accidents, schizophrenia, greater activity level, and higher sensory threshold. The present findings associate KAE reducing scores with the paramenstruum. Is it possible that relative to the rest of the cycle, women at paramenstruum show more delinquent behavior, more accidents, higher incidence of schizophrenic symptomatology, higher activity levels, and higher sensory thresholds?

The findings for the first three of these five domains show just this pattern. Relative to the rest of the cycle, there is significantly higher incidence during the paramenstruum of (a) crime (Dalton, 1961), unpremeditated acts of violence (Morton et al., 1953), and disorderly behavior among prisoners (Dalton, 1961); (b) accidents (Dalton, 1964); and (c) admission of newly hospitalized schizophrenics (Dalton, 1959) and hospital emergency ward treatment of schizophrenics (Glass et al., 1971).

Regarding the fourth domain, activity level, Morris and Udry (1969, 1970) report in two samples evidence that greater activity level (assessed by pedometer) occurs at the beginning and end of the cycle. Three peaks of activity were found—the largest around the time of ovluation, and two others, one occurring early in menstruation and the other in the premenstrual week. Although one might *describe* these curves as U-shaped (with an additional peak in the middle, much like our curves), no statistical test for curvilinearity was reported. At best, one can say that the observed data are consistent with the KAE curve over the menstrual cycle.

The results from the fifth domain—laboratory studies of sensory thresholds—are mixed. Only one study (of olfactory sensitivity) supports our expectation that higher sensory thresholds should occur at the beginning and end of the menstrual cycle (Vierling & Rock, 1967). In contrast, a study of visual threshold (Diamond, Diamond, & Mast, 1972), although reporting high threshold during menstruation, observed low threshold during the premenstrual week. A different pattern was reported for taste threshold (Glanville & Kaplan, 1965), where the lowest thresholds were

observed during menstruation as compared to two other periods during the cycle.

What conclusions can be drawn from these findings? With respect to sensory thresholds, the results are confusing. This may well mean that the parallel that we were seeking to draw between KAE and the menstrual cycle and between thresholds and menstrual cycle does *not* obtain. Another possibility is that these findings may reflect a problem in the threshold methodology employed (i.e., a confounding of sensitivity with response bias). Wong and Tong (1974) recently applied signal detection theory to the menstrual cycle/two-flash threshold relationship. They showed that a failure to distinguish between changes in response criterion and changes in sensitivity (a failure true of each of the threshold studies reviewed above) can considerably distort the relationship between threshold sensitivity and menstrual cycle. It remains an issue for future research to determine which of these two possibilities is most likely.

The first four domains reviewed each involved naturalistic observation, and only the last domain involved laboratory investigation. Ordinarily, one would give greater weight to studies based on laboratory research, because of the greater precision and greater control of extraneous variables normally associated with this methodology. Here, only sensory threshold studies used laboratory methods, but certain methodological limitations may be involved. Under these circumstances, there is little basis for weighting the laboratory evidence heavily and discounting the evidence from the domains involving naturalistic observation.

For these four domains, behaviors related to reducing in the KAE–trait literature show greater association with the cycle's beginning and end. For each domain, other possible explanations for this curvilinear pattern exist (see next section). Yet, within the limitations of the existing evidence, there is a convergence both with our curvilinear hypothesis and with the present curvilinear KAE findings. It is also noteworthy that recent menstrual cycle literature reviews (see the introductory sections of this article) concur that consistent and replicable menstrual cycle findings have been reported for criminal behavior and for psychiatric crises (which does subsume schizophrenic crises as one important component).[12] Thus, for two of these four domains, there is the most agreement that behavioral variation does occur over the cycle. It would be worthwhile to explore whether other behaviors known empirically to correlate with KAE show a similar curvilinear pattern over the menstrual cycle.

Possible Theoretical Implication

Our hypothesis regarding KAE was based, in part, on the assumption that the postulated SIM mechanism varies curvilinearly over the cycle. The finding that KAE shows the predicted curvilinear pattern thus constitutes one basis for inferring that the underlying process of SIM (presumed to underlie individual differences in KAE and thus to mediate the relationship between KAE and various external behaviors) also varies curvilinearly over the menstrual cycle. Obviously, this type of inference requires additional independent confirmation, preferably from other procedures that assess the postulated process (for example, the average evoked response measure of reducing–augmenting).

Suppose that future research clearly establishes that amount of activity level and incidence of criminal behavior, schizophrenic symptomatology, and accidents vary curvilinearly over the cycle. We would then tentatively offer the single parsimonious explanation that the modulator mechanism varies curvilinearly over the menstrual cycle and that this variation mediates the cyclic pattern observed for these four behavioral domains. There are various other alternative hypotheses that might also explain the cyclical pattern observed for any one of these domains. Dalton (1964), for example, explained sev-

---

[12] Although there is general agreement that incidence of "psychiatric crises" shows periodicity over the menstrual cycle, it is important to add that three studies have additionally indicated that the particular phenomenon of concern here, schizophrenic symptomatology, also shows such periodicity (i.e., Dalton, 1959; Glass et al., 1971; Jacobs & Charles, 1970).

eral of these findings in terms of cyclical variations in fatigue over the cycle. Parlee (1974) and Sommer (1973) have enunciated a social expectancy hypothesis that might account for the crime, accident, and psychiatric crises findings. Based on the known relationship between KAE as an index of trait and these same domains, we are here simply advancing a new, promising hypothesis. No claim is made that all possible alternative hypotheses have been precluded. We suggest that SIM may provide a useful theoretical foothold for understanding certain types of behavioral variation across the menstrual cycle. Further research assessing the implications of SIM formulations for the menstrual cycle seems warranted.

A General Implication for Social Expectancy Research

Finally, this study has a general implication for research areas in which social expectancy effects are a possible confounding variable. Undeniably, there is a cultural stereotype that certain kinds of pain and discomfort occur at the paramenstruum and another stereotype that behavioral decrements of various sorts (for example, poorer work performance) also occur at this time. But either or both of these stereotypes may also reflect true underlying phenomena. One approach to this problem is (a) to generate a hypothesis based on the assumption that a cultural stereotype—in this case, that the internal stimulation of pain and discomfort is greatest at the paramenstruum—is, at least in part, true and (b) then to test this hypothesis with respect to some measure—such as KAE—that is sufficiently unfamiliar to the subject so that no systematic social expectations exist. In general, a positive finding would offer support for the idea that the particular cultural stereotype involved reflects, at least to some degree, a true, underlying phenomenon. In this study, our positive findings regarding KAE offer some support for the assumption that aversive internal stimulation is greatest at the paramenstruum.

Evaluative Judgments of Aspects of Life as a Function of Vicarious Exposure to Hedonic Extremes

Marshall Dermer, Sidney J. Cohen, Elaine Jacobsen, and Erling A. Anderson
University of Wisconsin—Milwaukee

In two experiments, the hypothesis was corroborated that vicarious exposure to hedonic extremes—especially the hedonically negative—results in contrast regarding evaluative judgments of aspects of life that have evolved or been acquired in the course of life *beyond* the laboratory. In Experiment 1, participants who wrote about hedonically negative events occurring at the turn of the century expressed greater satisfaction on a composite index of present life quality than participants who wrote about hedonically positive events. In Experiment 2, participants who wrote about hedonically negative events, personal tragedies, scored higher on a composite index of satisfaction with life, health, and physical appearance than participants who wrote about hedonically positive events. The findings for the composites corroborate a comparison level model of evaluative judgment. The findings for individual items, however, suggest that aspects of life are not evaluated in terms of a single utility scale and standard—the comparison level. Other findings are discussed that appear to contradict a simple affective model of evaluation in which the positivity of evaluations is postulated to increase with the positivity of affective states.

A number of psychologists have generalized perceptual (Helson, 1964) and judgmental (Volkmann, 1951) principles, corroborated in the traditional experimental psychology laboratory, to social judgment. The most well-known generalization is that of Thibaut and Kelley (1959) who proposed a theory of the evaluation of outcomes resulting from social interaction. Although outcomes might differ in their specifics, it was assumed that all outcomes could be characterized in terms of their utility or hedonic value. The comparison level was conceptualized as a "psychologically meaningful midpoint for the scale of outcomes—a neutral point of satisfaction–dissatisfaction," (p. 81) and was defined as the "average value of all the outcomes known to the person (by virtue of personal or vicarious experience), each outcome weighted by its salience (or the degree to which it is instigated for the person at the moment)" (p. 81). An outcome, therefore, is judged to be positive or negative to the extent that its hedonic value is, respectively, above or below the comparison level.

Comparison level theory has been corroborated in a number of studies in which satisfaction with outcomes attained *within* experiments has increased as a function of manipulations hypothesized to lower the comparison level (e.g., Brickman, 1975; Friedland, Arnold, & Thibaut, 1974). Judgmental theories, however, apply to the evaluation of outcomes that are of greater importance to individuals than those usually bestowed upon participants in laboratory experiments. Thibaut and Kelley, for example, illustrated

their theory in terms of marital satisfaction. Volkman (1951, p. 286) also presumed the generality of judgmental principles. More recently, Brickman and Campbell (1971) generalized adaptation level theory (a conceptual cousin of comparison level theory) to satisfaction with, for example, personal wealth and competence. These generalizations are intriguing, but are without direct experimental support.

In this report, two experiments are presented in which the generality of comparison level theory was tested for evaluations of *important and often vital life outcomes that have evolved or been acquired in the course of a participant's life beyond the laboratory.* Furthermore, a condition in which participants were vicariously exposed to the hedonically negative was common to both experiments. The importance of this condition in testing comparison level theory, for this judgmental domain, is emphasized.

Experiment 1 [1]

In the past 10 years, a social indicator movement has evolved in which it has been proposed that the well-being of the nation can best be assessed by measuring a broad range of variables. Andrews and Withey's (1976) respondents, in particular, indicated their feelings regarding various aspects of life along rating scales similar to those used in laboratory studies of contrast. Furthermore, the "objects" of judgment (for example, the respondent's life as a whole and standard of living) differed from those of previous laboratory studies of contrast. The study of contrast in relation to judgments of the quality of life offers, consequently, an opportunity to replicate the response assessment methodologies of previous experiments and to generalize comparison level theory to a new class of stimuli. Furthermore, although the theoretical orientation of the present report tends toward linguistic rather than perceptual or subjective interpretations of contrast (see Manis, 1971) and comparison level theory (see Upshaw, 1969), as Andrews and Withey (1976) have noted, "anything that can be done to improve the human lot that is reflected as felt improvement is a condition to be coveted" (p. 10).

Hedonic Manipulation

In the present experiment, comparison level theory was tested by presenting historical information regarding life at the turn of the century. In the "good old days" condition, life was presented as the embodiment of traditional American ideals. For example, educational instruction was described as personalized, and students were depicted as having excellent foundations in reading, writing, and arithmetic; the air was clean and the water pure; there was time for people to genuinely relate to one another; food was wholesome and nutritious; people enjoyed their work and took pride in the products and services they provided; and government was efficient. In the "bad old days" condition, a description was presented of what historically appears to have been the plight of the vast majority of Americans. This information and the contrast principle are described in Otto Bettmann's (1974) prefatory remarks to his *The Good Old Days—They Were Terrible!*:

> I have always felt that our times have overrated and unduly overplayed the fun aspects of the past. What we have forgotten are the hunger of the unemployed, crime, corruption, the despair of the aged, the insane and the crippled . . . In most of our nostalgia books . . . the period's dirty business is swept under the carpet of oblivion. What emerges is a glowing picture of the past, of blue-skied meadows where children play and millionaires sip tea.
>
> If we compare this purported Arcadia with our own days we cannot but feel a jarring discontent, a sense of despair that fate has dropped us into the worst of all possible worlds. (pp. xii–xiii)

Female students evaluated the present quality of life at the beginning of the semester and some weeks later, immediately after having been exposed to one of the experimental conditions. It was generally hypothesized, on the basis of comparison level theory, that pretreatment-to-posttreatment changes in evaluations would be more positive in the

[1] Special thanks are due Linda S. Mezydlo and David Stamm for preparing stimulus materials and helping conduct this experiment.

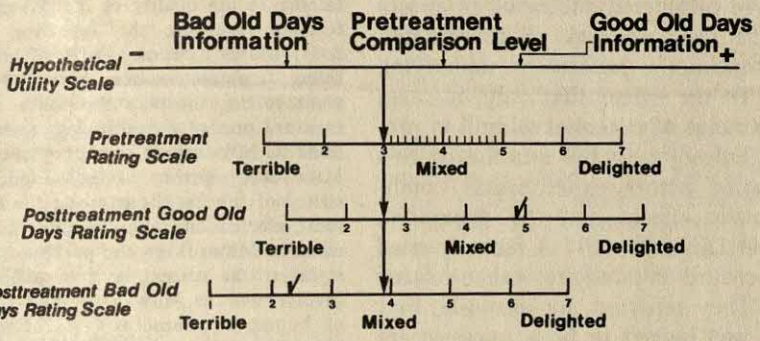

Figure 1. Location of pretreatment comparison level and information presented in experimental conditions, in relation to a hypothetical utility scale and rating scales.

bad than in the good old days condition. In particular, it was hypothesized that evaluations of present life quality would increase from pretreatment to posttreatment in the bad old days condition (positive contrast) but tend to decrease (negative contrast) somewhat or remain unchanged in the good old days condition.

The prediction of differential absolute magnitudes of contrast across experimental conditions and therefore a *stronger* test of comparison level theory in the hedonically negative than in the positive condition is illustrated in Figure 1. As indicated on the uppermost horizontal (utility) scale, the good old days information was assumed, by virtue of conveying traditional American values, to be closer in hedonic value to participants' pretreatment comparison levels than the bad old days information. The second horizontal line represents the pretreatment rating scale, centered at the hedonic value of the pretreatment comparison level. As Upshaw (1969, p. 347) has noted, comparison level theory implicitly assumes that the "origin" or midpoint of each judge's reference scale is anchored at the comparison level. The third horizontal line represents the posttreatment rating scale in the good old days condition, which has been shifted about three eighths of a unit upward in relation to the pretreatment rating scale. This shift follows from the definition of the comparison level as the average of all known outcomes, each outcome weighted by its salience, although the absolute magnitude of the shift is arbitrary. The fourth horizontal line represents the posttreatment rating scale in the bad old days condition, which has been shifted about seven eighths of a unit downward in relation to the pretreatment rating scale. Again, the absolute magnitude of the shift is arbitrary but is consistent with the definition of the comparison level as an average—the assumed hedonic value of the bad old days information and the magnitude of the shift postulated in the good old days condition.

The vertical line cutting across the three rating scales in Figure 1 represents an aspect of life that was evaluated 3 on the premeasure. As a consequence of the hypothesized scale shifts, its posttreatment evaluation is 2.7 in the good old days condition (a shift of .3 unit downward) and 3.9 in the bad old days condition (a larger shift of .9 unit upward). Finally it is important to note that although the posttreatment scales are postulated to shift, the assumptions just mentioned imply that posttreatment evaluations of the bad old days information in the bad old days condition should more greatly depart from the posttreatment scale midpoint than corresponding evaluations in the good old days condition. This implication is illustrated by the location of check marks on the posttreatment scales.

Scale Anchoring

Mere prior exposure to a stimulus complex that contrasts with a stimulus under evaluation has not generally been considered sufficient for generating contrast effects (see Eiser & Stroebe, 1972, p. 48). Judgmental

theorists have considered anchoring processes in which the response scale is coordinated with the continuum putatively underlying judgments. To the extent that only one segment of the range of potential stimuli is presented *and* judged, with the location of this segment varied across experimental conditions, linguistic effects may be generated. Pepitone and DiNubile (1976) recently used such a procedure in studying crime-related judgments. They reported, for example, that a homicide was judged to be a more severe criminal violation when participants first had read *and* publicly judged the seriousness of an assault case than in a condition in which the first case was another homicide. The overt recording of the first judgment appeared to be a necessary condition for producing a contrast effect.

In the present experiment, an anchoring manipulation was also included. After participants had been exposed to the stimulus materials and had written about them, all participants indicated their feelings regarding the present quality of life in Milwaukee. In the unanchored condition, participants simply expressed their judgments in terms of aspects of present life quality. In the anchored condition, participants were required to first evaluate an aspect of their present life in terms of the quality of life in Milwaukee in 1900, *immediately before* expressing their judgment of the same aspect of present life quality. Theoretically, this manipulation should increase the salience of the hedonic information and consequently result in greater contrast because of greater shifts in comparison levels in the anchored than in the unanchored conditions.

Method

Participants

Seventy-three women enrolled in introductory psychology at the University of Wisconsin—Milwaukee participated in the experiment in exchange for extra credit in their courses. Women were selected as a matter of convenience.

Pretreatment Measures

At the beginning of the semester, a survey was distributed that included a series of questions pertaining to the quality of life. Women indicated their feelings regarding the following aspects of their lives: life as a whole; personal health; standard of living; amount of time for doing the things they want to do; the way the police and courts in this area are presently operating; present working conditions in Milwaukee; present quality of education in Milwaukee; quality of their food; the present efficiency of the fire department; the honesty of present local, elected officials; the present physical environment in Milwaukee—the purity of the air, lakes, and streams; the present level of public spirit and civic involvement in Milwaukee; and the present quality of human relationships (e.g., between family members, doctors and patients, and merchants and customers). Items were included that appeared relevant to the hedonic manipulation. Respondents answered each question by placing a check mark *anywhere* along a 67-point rating scale similar to that of Andrews and Withey (1976, p. 18):

1.....2.....3.....4.....
Terrible Unhappy Mostly dissatisfied Mixed

.....5.....6.....7
Mostly satisfied Pleased Delighted

Those women whose ratings were between Unhappy (12) and Pleased (56) were invited to participate several weeks later and randomly assigned to conditions.

Procedure

Participants were run in small groups ranging in size from 2 to 10 women and responded independently to materials. Participants were told that their conceptions of life in Milwaukee at the turn of the century were being studied. Specifically, they would be asked to write a description of a day in the life of a typical Milwaukeean living in 1900. Participants were told that since they were probably not intimately familiar with life in 1900, materials describing this era would be presented. Participants were instructed to imagine vividly what life was like in Milwaukee in 1900 and to take notes if they wished.

Audiovisual Materials and Presentation Procedure

In all conditions, participants viewed an identical series of 16 slides; materials susceptible to multiple interpretations were used. Accompanying each slide was a tape-recorded narrative by which hedonic information was manipulated. In the good old days condition, life was described positively, whereas in the bad old days condition negative aspects were emphasized. For example, portions of the narrative associated with a slide of an elaborate fountain

park were as follows:

(*Good old days*). Beautifully carved fountains such as this one on Kilbourn Avenue provided a cooling respite for Milwaukeeans and contributed to the relaxed, slow-paced, leisurely atmosphere of the turn of the century. Note the graceful, flowing lines of the artfully sculpted statue that was characteristic of the quality craftsmanship of the European immigrants. Fountains like this one supplied a thirsty public with cool drafts of crystal-clear spring or pure well water on sunny afternoons.

(*Bad old days*). This fountain, located in the middle of a dirt highway later known as Kilbourn Avenue, is an example of the poor public hygiene practices of the turn of the century. Horses, birds, dogs, as well as people, drank and washed themselves in this public germ spreader. People all drank from the same filthy communal drinking cup. It was not known for years that fountains such a this one and the public drinking cups used with them were transmission vehicles for tuberculosis, smallpox, and other dreaded diseases which tore at the heart of the community by exiling infected people to isolation, or to convalescent hospitals for extended terms. Most people struck down and killed by tuberculosis were between the ages of 18 and 30.

Some narratives were longer than others, but for a given slide the narratives were of approximately equal length across experimental conditions. After the presentation of each slide, participants were given 15 sec to vividly imagine the scene without the accompanying narrative. Overall, participants spent a total of 32 min viewing the slides, listening to the narratives, and taking notes.

Descriptive Task

A booklet was next distributed, in which participants first described their conceptions of a day in the life of a typical Milwaukeean by indicating what this person would be doing at 1-hour intervals beginning at 6:00 A.M. when the person woke up, and finishing at midnight when the person retired to bed. Only upon completing the descriptive task were participants instructed to proceed.

Posttreatment Measures and Anchoring Manipulation

Two sets of measures were assessed after the descriptive task. The first (Present) set was identical to the pretreatment measures. The second (Past) set was similar to the Present set, but participants judged their life in terms of the quality of life prevalent in 1900. For example, the Past item corresponding to the first pretreatment measure was: "How would you feel about your life as a whole if it were similar in quality to that of a typical Milwaukeean living in 1900?" The questions were introduced as a way that the researchers might better understand participants' conceptions and feelings regarding life in Milwaukee.

In the unanchored sequence, participants first completed the 13 items in the Present set before responding to those in the Past set. In the anchored sequence, participants completed the first item in the Past set before completing the first item in the Present set. The remaining items were presented in this alternating fashion.

Debriefing

After completing their ratings, participants were informed that for experimental purposes, a balanced historical description had not been presented and that four volumes depicting life in Milwaukee in 1900 had been placed on reserve at the library. Participants were encouraged to approach the experimenter if they had any questions they wanted immediately answered and to contact the first author if they had questions later. Finally, participants were asked not to discuss the study with others. After the data had been analyzed, a complete description of the study and the findings was mailed to all participants.

Results

Manipulation Check

Responses were averaged across the 13 Past items to form an index of the judged quality of life in 1900 (coefficient alpha, based on the pooled within-cell covariance matrix, was .91). A univariate Hedonic × Anchoring Condition analysis of variance revealed only a reliable hedonic main effect, $F(1, 69) = 181.11$, $p < .0001$. Participants in the good old days condition indicated that if their present lives were similar in quality to the life portrayed, they would feel on the average "mostly satisfied" ($M = 45.4$), or about 11 points above the scale midpoint (34), whereas those in the bad old days condition would feel "unhappy" ($M = 15.1$), or about 19 points below the scale midpoint. These findings are consistent with the assumed hedonic value of the stimulus materials, as illustrated by the location of the materials on the utility scale in Figure 1 and the check marks on the accompanying rating scales.

It is also important to note that univariate analyses of variance for each item in the Past set revealed reliable hedonic effects ($p <$

Table 1
Average Judgments of Present Life Quality—Composite

Condition	*n*	Pre-treatment	Post-treatment	Difference	$F(1, 69)$	*p*
Unanchored						
Good old days	19	39.7	39.7	.0	.00	1.00
Bad old days	18	38.5	41.0	2.5	3.49	.07
Anchored						
Good old days	18	39.7	37.9	−1.8	1.78	.19
Bad old days	18	39.1	44.9	5.8	18.56	.00005

Note. Scores range from 1 (Terrible), through 34 (Mixed), to 67 (Delighted).

.0001) generally consistent with the overall index. The major exception was for evaluations of the fire department, in which the evaluations in the good old days condition ($M = 32.4$), although more positive than those in the bad old days condition ($M = 10.4$), were just below the scale midpoint. Finally, it is important to note that the seven largest F ratios were detected for the personal health, police and courts, food, elected officials, physical environment, public spirit, and human relationship items.

Major Analyses

Life quality composite. Responses were averaged across the 13 pretreatment items (coefficient alpha = .70) and the 13 posttreatment items (coefficient alpha = .81) to form indexes of present life quality. These composites are presented in Table 1. Analysis of pretreatment-to-posttreatment differences revealed a hedonic main effect, $F(1, 69) = 14.12$, $p = .0004$, as well as a Hedonic × Anchoring interaction trend, $F(1, 69) = 3.62$, $p = .06$. The test for the anchoring main effect was not reliable ($p = .56$).

The reliable hedonic main effect is due to pretreatment-to-posttreatment change in evaluations being more positive in the bad ($M = 4.2$) than in the good ($M = -.9$) old days conditions. This finding corroborates the most general comparison level prediction. Furthermore, the more specific hypothesis of greater positive contrast in the bad old days condition than negative contrast in the good old days condition was also corroborated. Inspection of the tests in Table 1 for pretreatment-to-posttreatment simple effects explicitly reveals that the positive contrast hypothesis was weakly corroborated in the unanchored bad old days condition ($p = .07$) and strongly corroborated in the anchored bad old days condition ($p = .00005$). Negative contrast, that judgments would decline in positivity after participants were exposed to the good old days information, was, however, detected in neither the unanchored ($p = 1.00$) nor the anchored condition ($p = .19$). The Hedonic × Anchoring interaction trend is, as predicted, due to the difference between the good and bad old days conditions being more enhanced when judgments were anchored (the difference is 7.6) than when they were unanchored (2.5).

Individual items. To investigate whether all items were uniformly influenced by the treatments, pretreatment-to-posttreatment difference scores were calculated for each item and a multivariate analysis of variance was conducted.

A reliable multivariate anchoring main effect was detected, $F(13, 57) = 2.04$, $p = .03$. This effect appears to be due to evaluations of the fire department increasing in the anchored ($M = 8.8$) as compared to the unanchored ($M = 2.0$) conditions ($p < .003$).

Of greater interest, a reliable multivariate hedonic main effect was also detected, $F(13, 57) = 2.16$, $p = .02$. Pretreatment-to-posttreatment difference scores were reliably (at $p \leq .05$) more positive in the bad than in the good old days condition for all items listed in Table 2 except personal health ($p = .06$). Inspection of the Difference column in Table 2 for pretreatment-to-posttreatment

Table 2
Average Judgments of Present Life Quality—Individual Items

Item and condition	Pre-treatment	Post-treatment	Difference	$F(1, 69)$	p
Personal health					
Good old days	48.0	47.2	−0.8	0.26	.61
Bad old days	44.9	48.5	3.6	4.70	.03
Police and courts					
Good old days	36.4	31.7	−4.7	5.25	.02
Bad old days	33.1	35.9	2.8	1.81	.18
Quality of food					
Good old days	43.7	41.7	−2.0	1.15	.29
Bad old days	43.9	47.2	3.3	3.06	.08
Elected officials					
Good old days	33.8	28.3	−5.5	7.50	.008
Bad old days	33.6	33.9	0.3	0.02	.89
Physical environment					
Good old days	28.0	26.7	−1.3	0.52	.47
Bad old days	23.4	31.0	7.6	17.33	.00009
Public spirit					
Good old days	33.1	31.8	−1.3	0.48	.49
Bad old days	30.0	36.2	6.2	10.86	.002
Human relationships					
Good old days	37.0	32.2	−4.8	3.97	.05
Bad old days	34.9	43.4	8.5	12.14	.0009

Note. Scores range from 1 (Terrible), through 34 (Mixed), to 67 (Delighted).

changes in judgments reveals that, generally, evaluations tended to decrease in the good old days condition and increase in the bad old days condition. Furthermore, inspection of the F ratios indexing these changes suggests that, generally, increments in judgments (positive contrast) in the bad old days condition tended to be larger than decrements (negative contrast) in the good old days condition.

The hedonic main effect and pretreatment-to-posttreatment simple effect findings described above are consistent with the analyses reported for the composite. The multivariate test for the Hedonic × Anchoring interaction was, however, not reliable, $F(13, 57) = 1.49$, $p = .15$.

Discussion

Life Quality Composite

Comparison level theory most generally implies that pretreatment-to-posttreatment changes in judgments should be more positive in the bad than in the good old days condition. This is precisely what was detected, as indicated by the reliable test for the hedonic main effect, when pretreatment-to-posttreatment differences for the composite were analyzed. Furthermore, it was hypothesized that contrast effects would be greater in the bad than in the good old days condition. This is precisely what was detected, as indicated by the tests for pretreatment-to-posttreatment simple effects reported in the last two columns of Table 1. It must be noted, however, that whereas these tests are consistent with a more precise contrast hypothesis, the comparisons must be interpreted cautiously because of the absence of a no-treatment control group.

The results for the composite also support the hypothesis of greater contrast in the anchored than in the unanchored condition, although the test was just short of being reliable at conventional levels of significance. This finding is similar to that reported by Pepitone and DiNubile (1976), who detected

contrast only when judgments of an initial stimulus in a two-stimulus "sequence were 'anchored,' that is overtly recorded and thus publicly committed" (p. 448). It is not clear, however, on the basis of either study, which aspects of such anchoring manipulations are necessary for producing contrast. Whereas Pepitone and DiNubile have stressed public commitment, according to comparison level theory, merely requiring participants to judge *but not publicly record initial judgments* should be sufficient to induce or enhance contrast, by virtue of increasing the salience of the hedonic value of the prior stimulus.

Individual Items

The contrast hypotheses were corroborated for 7 of the 13 life quality items. The pattern of reliable hedonic effects for the set of items appears clearly due to differential manipulation of aspects of life. Those aspects of life along which the general contrast hypothesis was corroborated were those most strongly manipulated.

Finally, it will be recalled that a reliable anchoring effect was detected for the fire department item. This finding, that evaluations of the fire department increased more in the anchored than in the unanchored conditions *across* levels of the hedonic factor, can be reconciled with adaptation level theory if not with comparison level theory.[2] Recall that the manipulation check pertaining to the efficiency of the fire department indicated that evaluations were often below the scale midpoint in the good old days condition and even more so in the bad old days condition. The net result in either hedonic condition was to increase the salience of how bad the fire department was in 1900. In the anchored conditions, the manipulation checks were collected before the evaluation of the fire department's present efficiency, and thus, greater salience and positive contrast would be expected in this condition.

Theoretical Implications

The present findings, although corroborating comparison level theory, suggest that the theory may not be sufficiently refined to adequately represent the complexities of evaluative judgment. Upshaw (1969) has emphasized an important theoretical distinction between comparison and adaptation level theories. Although outcomes might differ in their specifics, according to comparison level theory, all outcomes are judged in terms of a single utility scale such that "a nagging wife, a 10% salary raise, and a slice of apple pie are all evaluated in terms of a single CL [comparison level]" (pp. 347–349). This conception of the comparison level as a generalized hedonic standard of judgment would imply that contrast effects should have been detected, within the limits of experimental error, across all 13 measures of life quality. As indicated, however, the general contrast hypothesis was corroborated for only 7 of the measures. (The differential impact of the hedonic manipulation upon the measures is not due to differential experimental error.)[3] According to an adaptation level model of judgment, there is a different reference scale for each aspect of life, with each scale having a particular adaptation level (Upshaw, 1969, p. 347). This model of judgment is consistent with the finding that the strongest contrast effects were observed along those dimensions that were most strongly manipulated, and the anchoring main effect detected for evaluations of the efficiency of the fire department.

Experiment 2[4]

In Experiment 2, we attempted to constructively replicate Experiment 1 by essentially following Abraham Maslow's (Maslow, 1972) suggestion regarding exercises in deprivation:

> All you have to do is to go to a hospital and hear all the simple blessings that people never before realized *were* blessings—being able to urinate, to

---

[2] Upshaw (1969) has distinguished between adaptation and comparison level models of judgment. This distinction is presented in the next section.

[3] These error terms are for the analyses of pretreatment-to-posttreatment difference scores.

[4] Special thanks are due Margaret Grade and Betty McMackin for help in conducting this experiment and Carol Schultz for her extensive assistance in collecting and developing stimulus materials.

eep on your side, to be able to swallow, to scratch n itch, etc. Could *exercises* in deprivation educate s faster about all our blessings? (p. 108)

Vomen who had completed pretreatment easures earlier in the semester were asked o imagine vividly a series of events. In the edonically negative condition, the events ere personal tragedies, whereas in the comarison condition the events were all positive. fter imagining *each* event, participants decribed what they would do, think of, and eel. Later, they expressed their level of satisaction with various aspects of life, including heir life in general, health, and physical apearance, on scales identical to the pretreatnent measures.[5] Given the results of an earlier xperiment (see Footnote 5), and given that he latter aspects of life appeared a priori to e most strongly manipulated across condiions, it was predicted that on a composite of hese measures, pretreatment-to-posttreatment changes in evaluation would be more positive in the hedonically negative than in the hedonically positive condition. This prediction, of course, is analogous to the general contrast prediction, which was strongly corroborated in Experiment 1 and was the major hypothesis tested in the study.

Participants also described their moods. According to a simple affective model of evaluation, the positivity of evaluative responses should covary directly with the positivity of affective states (Byrne, 1971, chapter 13). Both comparison and adaptation level theories, however, suggest that evaluations on the composite index would be most positive in the hedonically negative condition. The mood descriptions also served as a manipulation check.

Method

Participants

Eighty-three women enrolled in introductory psychology at the University of Wisconsin—Milwaukee participated in the experiment in exchange for extra credit in their courses. Women were again selected as a matter of convenience.

Pretreatment Measures

At the beginning of the semester, a survey was distributed that included a series of questions regarding the respondent's satisfaction with her life, health, physical appearance, relations with other people, sex life, and financial situation. Respondents answered each question by placing a check mark *anywhere* along the following rating scale:

1..... 2..... 3..... 4.....

Exceptionally dissatisfied | Very dissatisfied | Dissatisfied | Slightly dissatisfied

.... 5..... 6..... 7..... 8

Slightly satisfied | Satisfied | Very satisfied | Exceptionally satisfied

Responses to this 71-point scale were assigned integers from 10 (Exceptionally dissatisfied) to 80 (Exceptionally satisfied). Those women whose ratings were between 30 and 65 were invited to participate several weeks later and were randomly assigned to conditions. (Several women participated although they had not completed the "sex life" question.)

Procedure

Participants were run in small groups ranging in size from two to seven persons and responded independently to the materials. Each session lasted about 2 hours. All instructions and questions were contained in a single booklet.

Instructions. At the beginning of each session, participants were informed that they would be asked to read and respond to a series of articles and that their responses would be confidential. It was also explained that at any time they could decline to answer a question or participate further, but would receive full credit toward their psychology course.

Participants were told that the ability of people to vividly imagine "life events" was being studied. They anticipated reading a series of life events,

---

[5] Before the present series of experiments had been conducted, a study conceptually similar to Experiment 2 had been run (Fisher, 1976). Women role played either being slow walkers or having been in an automotive accident and confined to wheelchairs for the rest of their lives. After traveling about campus for an hour and discontinuing role playing, participants in the hedonically negative condition tended to express more positive judgments on a composite index of satisfaction with life, health, and physical appearance than participants in the control condition. For various methodological reasons (e.g., the absence of pretreatment measures and some participants failing to comply with the role-playing instructions) the difference between conditions was not reliable, $F(1, 78) = 1.65$, $p = .10$, directional alternative. We believed the findings to be suggestive, however, and consequently designed a more precise study—Experiment 2.

imagining the events happening to themselves and describing their reactions to the events.

Life events. In the hedonically negative condition, participants successively imagined (a) that they were severely burned and permanently disfigured—especially their face and hands—as a consequence of a gas explosion that destroyed their home or apartment and killed someone they dearly loved; (b) that they were blind; (c) that they were in an automobile accident that resulted in their confinement to a wheelchair for the rest of their lives; and (d) that they were severely suffering from Hodgkin's disease, a cancer of the lymphatic system that most often attacks young adults. In the hedonically positive condition, participants successively imagined that they were (a) winners of an all-expenses-paid tour for themselves and a friend to southwestern Europe and Morocco; (b) multimillionaires who with their loved one enjoyed a spectacular world cruise on the Queen Elizabeth 2; (c) well-paid private secretaries who travelled through northeastern Europe with their wealthy employer; (d) and winners of an all-expenses-paid vacation of their own design, for themselves and a friend, in Missouri.

To stimulate participants' imaginations, in the negative condition women read appropriate articles from the medical and rehabilitation literature, whereas in the positive condition they read travel brochures. Participants could not proceed to a new life event until they had read and described their reactions to earlier life events.

Posttreatment Measures

Upon completing the last life event, subjects were told that the role-playing task was over and that additional information was being collected to better understand responses. Participants first described how they felt while role playing, by completing the Nowlis (1970) Mood Adjective Check List. Later, they described their satisfaction with the six aspects of life assessed at the beginning of the semester, on identical rating scales. Participants then completed a second set of mood scales to describe their current mood. The last question in the booklet asked participants to describe anything that might help the researchers understand participants' responses. This question was included generally to enhance an understanding of the effects of the treatment and to check for experimental demand. Although many women wrote extensively, especially in the hedonically negative condition, no one indicated knowledge of any of the hypotheses being investigated.

Debriefing

After the data were analyzed, a complete description of the study and the findings was mailed to all participants. Those wishing additional information were invited to discuss the study with the researchers.

Table 3
Average Mood Scores as a Function of Experimental Condition and Phase

Factor	Condition: Hedonically negative (n = 42)	Condition: Hedonically positive (n = 41)	Univariate hedonic tests, $F(1, 81)$
	During role-playing task		
Elation	5.2	9.8	55.82
Anxiety	7.8	4.7	39.05
Sadness	7.8	4.4	45.86
	After satisfaction ratings		
Elation	6.3	6.3	0
Anxiety	5.9	4.1	13.15
Sadness	5.3	3.9	10.85

Note. High scores indicate greater elation, anxiety, and sadness. The range of possible scores for elation is 4 to 16, and for the remaining factors is 3 to 9. All nonzero F statistics are reliable at $p < .002$.

Results

Manipulation Check

Multivariate analyses of variance for mood during the role-playing task, $F(3, 79) = 34.40$, $p < .0001$, and after the satisfaction ratings were made, $F(3, 79) = 5.09$, $p < .003$, indicated reliable hedonic effects. As indicated in Table 3, participants' reports of mood were generally more negative in the hedonically negative than in the hedonically positive condition.

Major Analyses

Satisfaction composite. The three satisfaction measures hypothesized to be most influenced by the treatments were averaged to form a composite (the alpha coefficients for the pretreatment and posttreatment indexes were, respectively, .52 and .59). An analysis of variance of pretreatment-to-posttreatment differences revealed, as predicted, greater positivity in judgments of satisfaction in the hedonically negative than in the hedonically positive condition, $F(1, 81) = 3.32$, $p < .04$, directional alternative. As indicated in Table 4, participants' judgments of satisfaction increased an average of 4.9 points in the hedoni-

Table 4
Average Judgments of Satisfaction

Variable	Pre-treatment	Post-treatment	Difference	$F(1, 81)$	p
	Hedonically negative condition ($n = 42$)				
Composite	53.6	58.5	4.9	20.37	.00002
Life	55.0	61.1	6.1	18.78	.00004
Health	54.3	61.2	6.9	15.96	.0001
Physical appearance	51.4	53.2	1.8	1.77	.19
	Hedonically positive condition ($n = 41$)				
Composite	53.8	55.9	2.1	3.65	.06
Life	55.0	56.3	1.3	0.83	.36
Health	55.3	57.8	2.5	2.04	.16
Physical appearance	51.0	53.6	2.6	3.61	.06

Note. Scores range from 10 (Exceptionally dissatisfied), through 45, the midpoint, to 80 (Exceptionally satisfied).

cally negative condition but only 2.1 points in the positive condition. The tests for pretreatment-to-posttreatment simple effects, in the last two columns of Table 4, reveal the hedonically negative condition to be associated with the largest increment in evaluations.

It will be recalled that according to a simple affective model of evaluation, the positivity of evaluations increases with the positivity of affective states. The present findings contradict this model, since judgments of satisfaction were most positive in the hedonically negative condition. Nor does it appear that the positivity of evaluative responses increases with *changes* toward more positive affective states. According to such a revised model, the participants in the hedonically negative condition judged their lives most positively because of the affective "relief" resulting from the termination of the role-playing task. Contrary to the revised model, as participants' moods in the hedonically negative condition decreased (from first to second assessment) in terms of sadness and anxiety, their pretreatment-to-posttreatment changes in judged satisfaction, on the composite, *also decreased*, $r(40) = .34$, $p < .05$, for sadness; $r(40) = .30$, $p < .06$, for anxiety. Changes in elation did not covary ($r = -.01$) with changes in the composite.

Individual items. For each item, pretreatment-to-posttreatment difference scores were calculated. The omnibus multivariate hedonic test was reliable, $F(3, 79) = 2.65$, $p = .05$, as were the univariate tests for satisfaction with life, $F(1, 81) = 5.63$, $p < .01$, directional alternative, and health, $F(1, 81) = 3.23$, $p < .04$, directional alternative. As indicated in Table 4, pretreatment-to-posttreatment increments in judged satisfaction with life and health were greater in the hedonically negative than in the hedonically positive condition. The weak trend for judgments of satisfaction with physical appearance is contrary to that hypothesized and, of course, is not reliable, using a directional statistical decision rule, $F(1, 81) = .15$.

Similar analyses of pretreatment-to-posttreatment change were conducted for judgments of satisfaction with relations with other people and financial situation. Whereas the means for the relations item were in the direction specified by comparison level theory, $F(1, 81) = 2.00$, $p < .08$, directional alternative, the means for the financial item were in the opposite direction, $F(1, 81) = .02$. Furthermore, although the absence of pretreatment measure scores for some participants precluded a pretreatment-to-posttreatment analysis of satisfaction with sex life, the posttreatment means were also opposite to what would be expected if the comparison level, $F(1, 81) = .71$, were a generalized standard.

Discussion

Satisfaction Composite

The finding that pretreatment-to-posttreatment changes in judgments of satisfaction were reliably more positive in the hedonically negative than in the hedonically positive condition corroborates the major prediction derived from comparison level theory. Furthermore, it is interesting to note that as in Experiment 1 (bad old days condition), the hedonically negative condition was associated with the largest increments in evaluations. Although the stimulus material was not judged by participants in terms of hedonic value (as in Experiment 1), the greater potency of the hedonically negative material may have resulted from its departing more from participants' pretreatment comparison levels than did the hedonically positive information.

The findings for the satisfaction index do not appear to corroborate Byrne's (1971) affective model of evaluation, since judgments of satisfaction were greatest in the most affectively negative condition. Obviously, more research is needed to delimit the generally accepted positive relationship between affective states and evaluations.

Individual Items

The contrast hypothesis was corroborated for two—life and health—of the three items comprising the satisfaction composite. Evaluative judgments of physical appearance were virtually uninfluenced, although the within-cell experimental error for this item (see Footnote 3) was slightly smaller than the error associated with the items yielding reliable contrast effects. Furthermore, it will be recalled that satisfaction regarding three aspects of life besides the composite items were measured and analyzed, but contrast effects were not generally detected. Although comparison level theory may be of heuristic value, these findings do not appear consistent with the assumption that all outcomes are judged in terms of a single utility scale and standard—the comparison level.

General Discussion

Summary of Major Findings

These experiments corroborate the hypothesis that vicarious exposure to hedonic extremes—especially the hedonically negative—results in contrast effects regarding evaluative judgments of aspects of life that have evolved or been acquired in the course of life *beyond* the laboratory. Although the present results are generally consistent with comparison level theory, the findings appear better described by an adaptation level model of judgment (Upshaw, 1969, p. 347). Furthermore, the finding that the hedonically negative condition of Experiment 2 was associated with the most negative moods, but the most positive judgments, appears to contradict Byrne's (1971) affective model of evaluation.

Potential Limitations

Participant sex. Although only women participated in the present studies, the findings should hold for males, since contrast effects have been detected with males in other studies (e.g., Brickman, 1975).

Treatment complexity. The treatments used in the present experiments were complex. It is, therefore, not precisely known which aspects of the treatments—especially the hedonically negative treatments—mediated effects. Clearly, participants were not merely exposed to stimuli. For example, across both experiments, participants described reactions to the stimulus materials before evaluating aspects of life.

Magnitude of effects. In relation to the maximum contrast effects that could be detected in these experiments, the effects of the hedonically negative materials, though statistically reliable, were small. A number of considerations are relevant to this result:

1. Several participants indicated that the hedonically negative materials had created a conflict. On the one hand, they were inclined to increase the positivity of their judgments, yet they felt that this was inappropriate, since their judgments were typically not so positive. These participants reported expressing their more typical judgments on the post-

treatment measures, thus hindering the detection of large contrast effects.

2. In designing these experiments, it was assumed that most participants had not been extensively or recently exposed to hedonically negative information and that the hedonic value of such information consequently was substantially below participants' pretreatment comparison levels. These considerations would suggest the production of large contrast effects. According to Thibaut and Kelley (1959), however, the weights associated with the comparison level reflect the "salience" of outcomes, where "salience" refers to the extent that an individual might think about outcomes before judgment. But, as illustrated by the mood ratings in Experiment 2, hedonically negative outcomes may have immediately aversive properties. Thinking, for example, of injury, disease, or death generally elicits aversive emotional responses, amounts to self-punishment, and may therefore ordinarily be avoided.[6] Consequently, the salience and weighted contribution of the hedonically negative to the comparison level may be small.

3. Strictly speaking comparison and adaptation levels are weighted averages. The determinants of values and weights, however, have not been precisely specified. Although exposure to hedonically negative information for more than an hour, as in Experiment 2, may appear substantial, the contribution to comparison or adaptation levels may be small, since these constructs reflect all of a participant's previous experience.

Beyond the Hedonically Positive

Psychologists appear, in general, to have assumed that individuals are primarily oriented towards the hedonically positive when making assessments, although the psychological basis for this assumption has not always been specified. Festinger (1954) made this assumption for the assessment of abilities when he postulated that individuals compare themselves with those performing better. Numerous research instruments involve a comparison between a respondent's description of his or her present status and "ideal" status, and the concept of relative deprivation, of course, depends upon an individual not having that which he or she desires (see Cook, Crosby, & Hennigan, 1971). But if our theories are general, they should also explain when and how the hedonically negative may influence judgment. The young students we most often study may be bombarded with advertisements rendering the hedonically positive salient, and they may believe that they will always be healthy and their outcomes constantly improving; but as theorists we should not be blinded by these aspects of our culture.

Thibaut and Kelley (1959) attempted to specify a psychological theory of outcome salience in proposing that salient outcomes are those that an individual believes he or she can to some degree control. Since vicarious exposure to the hedonically positive may provide information about response-positive reinforcement contingencies (see Berger, 1977) and consequently mediate positive reinforcement, it is not surprising that individuals may attend to those achieving more positive outcomes and think about these activities and subsequent outcomes. Such behavior may momentarily decrease judgments of satisfaction with current outcomes but may mediate more positive future outcomes. Eventually, however, there may be little or no possibility of achieving the hedonically positive! This may be true, for example, because of injury, disease, old age, or social constraints. Under these circumstances, the hedonically negative may become salient even though it may

---

[6] Several months after Experiment 2 was completed, but before debriefing, we contacted participants by telephone and solicited their reactions to the experiment. The participants in the hedonically positive condition appear to have had some trouble recalling the experiment and generally did not express much interest in it. The participants in the hedonically negative condition, however, appeared to have little trouble recalling the study, thought participation was a valuable experience, and were eager to learn more about the study. Although thinking about the hedonically negative was aversive, the participants almost without exception deemed the experience valuable. Several participants reported being happier with their lives a few days after participation. One participant, however, reported discerning the major hypothesis the day following the experiment.

momentarily elicit aversive emotional behavior. The hedonically negative may provide information about response-negative reinforcement contingencies and thus facilitate an individual's avoiding outcomes far more aversive than those immediately resulting from vicarious exposure to, or thinking about, the hedonically negative. And, of course, as illustrated in the present experiments, such information would be expected to enhance judgments of satisfaction with present life outcomes.

Finally, it is interesting to note the applied implications of the present experiments. The students in Experiment 1 do not appear to have had much knowledge of the plight of the masses and the details of day-to-day life in earlier times. American historians only as recently as the 1960s have come to write history from the "bottom up" (see Thernstrom, 1964), although they were long aware that history has ordinarily been written and taught from the perspective of the bourgeoisie and aristocracy. The current findings suggest that it might be beneficial to incorporate descriptions of the lives of ordinary people into primary and secondary history curricula. Certainly 19th-century novelists have provided graphic descriptions. To paraphrase Sir Walter Raleigh, one may learn to be appreciative from comparing people's forepast miseries with one's own like errors and ill deservings. Similarly, the results of Experiment 2 suggest that we might more likely count our blessings if we were not so isolated from the hedonically negative.

Actor–Observer Differences in Information Inference and Causal Attribution

Susan V. Eisen
McLean Hospital
Belmont, Massachusetts

Two experiments were conducted to assess (a) differences in the information available to persons trying to understand the causes of their own behavior (actors) versus those trying to understand the causes of another's behavior (observers) and (b) the effects of information differences on causal explanations. In Experiment 1, actors reported positive behaviors to be less distinctive and more consistent with past behavior than did observers, whereas the reverse was true for negative behaviors. Consistent with this difference, actors attributed desirable behaviors more to their own internal dispositions than did observers, whereas the opposite occurred for undesirable behaviors. In Experiment 2, when all subjects were given the consensus, distinctiveness, and consistency information generated by actors in Study 1, both actors and observers attributed positive acts more to internal factors than negative acts. When given the information generated by the observers, neither actors nor observers exhibited this bias. Thus, when given the same information, actors and observers no longer showed differences in causal explanations.

Recent theory and research have suggested that under a variety of circumstances, causal explanations for one's own behavior differ from explanations of the same behavior performed by someone else (Jones & Nisbett, 1972; Monson & Snyder, 1977). Jones and Nisbett (1972) discussed three factors that may contribute to these differential perceptions of causality. They proposed that actors and observers differ in their visual perspectives, their motivations, and the information available to them.

The effects of visual perspective have received much attention, and results have generally supported the contention that actors tend to see the causes of their behavior as environmental, whereas observers view the causes of the same behavior as originating within the actor (Arkin & Duval, 1975; Nisbett, Caputo, Legant, & Maracek, 1973; Regan & Totten, 1975; Storms, 1973). Similarly, much research has focused on actor–observer attribution differences that appear to be motivationally based (e.g., Arkin, Gleason, & Johnston, 1976; Bradley, 1978; Miller & Ross, 1975; Sicoly & Ross, 1977; Snyder, Stephan, & Rosenfield, 1976; Stevens & Jones, 1976).

In contrast, the question of the effects of actors' and observers' informational differences on causal attribution has been relatively neglected. It is this question that the present research addresses. Jones & Nisbett (1972) suggested that because they know their own history, actors are in a better position than observers to assess how distinctive and consistent a current behavior is compared with past behavior. Although observers may know little about someone else's past behavior, they probably have an idea of whether they them-

This article is based on a dissertation submitted to the Department of Psychology, Brandeis University, in partial fulfillment of the requirements for the PhD degree. selves would (or did) perform the behavior (consensus). Thus, observers may evaluate an actor's behavior by comparing it with the behavior of others, while actors may evaluate their own behavior by comparing it with past behavior. These three types of information (distinctiveness, consistency, and consensus) were first proposed as useful for causal attribution by Kelley (1967) and were found to have a significant impact on perceptions of causality (Hansen & Lowe, 1976; McArthur, 1972; Orvis, Cunningham, & Kelley, 1975).

The difference in information available to actors and observers may contribute to divergent perceptions of causality (Jones & Nisbett, 1972). For example, if Mr. Smith fails to show up for a meeting, his supervisor may infer that Smith's unreliable behavior is widespread (low in distinctiveness and high in consistency) and that hardly anyone else fails to attend (low consensus). In line with Kelley's (1967) model, the supervisor would attribute Smith's transgression to his unreliable nature. On the other hand, Smith may know that he rarely misses meetings and attribute his absence to external factors. Consistent with the difference in information available to actors and observers, Hansen and Lowe (1976) found that in attributing causality for a behavior, actors relied more heavily on distinctiveness and consistency information, whereas observers favored consensus. However, to date there have been no attempts to ascertain whether actors think their behavior is more distinctive and less consistent with past behavior than observers think it is.

The purposes of the present research were (a) to investigate actors' and observers' reports of how they think others would behave in given situations (consensus) and their knowledge or assumptions about the distinctiveness and consistency of given behaviors; (b) to assess actors' and observers causal attributions for a variety of behaviors; and (c) to examine the effect on causal attributions of providing actors with the information reported by observers, and vice versa.

Assessment of actor–observer differences in information assumptions was accomplished in Experiment 1 by having actors and observers estimate consensus, distinctiveness, and consistency information for a series of behaviors. Causal attributions were studied in Experiment 2 by giving one group of subjects no information, another group the information generated (assumed) by actors in Study 1, and a third group, the information generated by observers in Study 1. This method is analogous to that used by Storms (1973). But, rather than reversing visual perspectives, actors' and observers' "informational perspectives" were reversed.

Experiment 1

Experiment 1 was designed to assess differences in actors' and observers' estimates of consensus, distinctiveness, and consistency surrounding each of 12 behaviors. For this purpose, 12 "personality–achievement inventory" items were devised, each indicative of a different behavior. Three valences (positive, neutral, and negative) and four categories (emotions, beliefs, actions, and accomplishments) of behavior were employed, yielding one item for each combination of valence and category. All subjects completed the items and were provided with false feedback informing them of the behavioral dimension each item measured. Actors' feedback referred to their own responses, while observers' feedback referred to the responses of another subject whose completed items they were shown. Based on the feedback, actors generated consensus, distinctiveness, and consistency for each of their own responses, while observers generated the same types of information for their matched actor's responses.

Choice of this methodology was guided by two major considerations: (a) In order for me to be able to generalize the findings, investigation of a variety of behaviors was desired, and (b) relatively novel behaviors, for which actors are not likely to have a vast store of distinctiveness and consistency information, had to be chosen in order for the information manipulations used in Study 2 to be believable. Since taking a "personality–achievement inventory" is a fairly novel experience in the lives of most people, it appeared to be a good mechanism for accommodating these considerations.

Table 1
Personality and Achievement Dimensions Represented by Each Item

Valence	Behavioral category			
	Emotions	Beliefs	Actions	Accomplishments
Positive	*Happy*/ Unhappy	*Progressive*/ Conservative	*Helpful*/ Unhelpful	Verbal reasoning *Correct*/incorrect
Neutral	*Excitable*/ Unexcitable	Skeptical/ *Naive*	Reserved/ *Outspoken*	Language skills *50%*
Negative	Affable/ *Hostile*	Tolerant/ *Intolerant*	Reliable/ *Unreliable*	Spatial relations Correct/ *incorrect*

Note. The italicized item represents the feedback given to subjects regarding their own (actors) or their matched actor's (observers) response.

Based on Jones and Nisbett's (1972) suggestion, it was predicted that (a) actors would estimate higher distinctiveness and lower consistency for their responses than would observers and (b) actors would be more certain of their distinctiveness and consistency estimates than would observers.

The predictions for consensus information were more complicated. Since observers as well as actors completed the inventory items, they knew whether they gave the same response as the person whose completed items they were shown. Since only 12 items were employed, observers could easily recall their responses. Thus, they already had "self-based" consensus information (Hansen & Donoghue, 1977). Consequently, it was predicted that (c) observers who gave the same response on an item as their matched actor (high self-based consensus) would estimate higher consensus than would actors, whereas observers who gave a different response (low self-based consensus) would estimate lower consensus than would actors; and (d) observers having high self-based consensus would be more certain of their consensus estimates than actors.

Method

Experimental Design

The experiment was a 2 × 2 × 3 × 4 design (Sex of Subject [male, female] × Role [actor, observer] × Valence of Behavior [positive, neutral, negative] × Category of Behavior [emotions, beliefs, actions, accomplishments]).

Subjects

Eighteen male and 18 female undergraduates volunteered to serve as subjects for research on "personality assessment," in partial fulfillment of an introductory psychology course requirement. Half the subjects of each sex were randomly assigned to serve as actors; the remaining subjects served as observers and were each "yoked" to a same-sex actor. That is, each observer was shown the responses of a same-sex actor and generated information for that actor's responses. Subjects were run individually by a female experimenter.

Personality–Achievement Items

Twelve forced-choice self-report items from a supposed "personality–achievement inventory" were constructed. Each item indicated a positive, neutral, or negative emotion, belief, action, or accomplishment. The nine personality behavior dimensions (emotions, beliefs, and actions) were selected from Anderson's (1968) likableness ratings of 555 adjectives. Positive behaviors were rated in the top 100, neutral behaviors between 240 and 300, and negative behaviors in the bottom 100. The behavioral dimensions selected appear in Table 1. Although the dimensions could be conceived of as traits, the items themselves dealt with specific, concrete situations. For example, the following item represented the happy–unhappy (positive emotion) personality dimension:

A. When I feel depressed, my friends are usually able to cheer me up.
B. When I'm dating someone special, I feel more cheerful than usual.

The three achievement items were actual tasks: an analogy, an anagram, and an embedded-figure problem.

Three randomly ordered blocks of four items each were constructed, with the restriction that an achieve-

ment task was always the last item in each block. This was done to facilitate timing of the problems. (The personality items were not timed.) Each of the three blocks was randomly ordered to yield three orders of items.

Procedure

Subjects were told that we were studying personality assessment techniques and that they would be asked to complete 12 items from a larger, widely used personality–achievement inventory. The items would be scored, the subjects would be told the results, and they would be asked some questions about their responses. Participants in the experiment were then asked to read the instructions, complete the first page containing three personality items, look at the example of the problem that was to follow on the next page, and then call the experimenter to time the "test" problem. The experimenter informed subjects how much time they would have to do the problem, instructed them to begin, and informed them when time was up. This procedure was followed until all 12 items were completed.

Actors. After completing the items, actors were left alone for approximately 3 minutes while the experimenter scored their inventories. Upon returning, the experimenter gave the subjects the scored items, along with written feedback and the dependent-measure questionnaire.

Observers. Upon completion of the inventory items, observers were told that their tests would be scored and feedback would be given later, but in the meantime, the experimenter would like them to look at someone else's completed and scored inventory and answer some questions about the other person's responses. The experimenter left the room, returning several minutes later with a same-sex actor's scored inventory and the dependent-measure questionnaire.

Feedback

The feedback (scoring) was presented in the dependent-measure booklet. At the top of each page appeared a personality or achievement dimension represented by one item, followed by a sentence specifying which end of the dimension the subject's response indicated. The dimensions were numbered to correspond to the numbers of the inventory items. Below is an example of one dimension and the feedback given:

> Subscale: HAPPY–UNHAPPY
> On this item you (actors)/this student (observers) gave the *happy*/unhappy response.

For each item, the end of the dimension that the response supposedly indicated (the italicized word) was circled in red ink to appear as if the feedback were tailored to the individual's response. In fact, everyone received the same feedback regardless of how the item was answered. Thus, even though subjects did not answer all the items in the same way, all were told that their responses indicated the same behavior. Debriefing revealed that subjects believed that the items were from an actual personality-achievement inventory and that the feedback was valid. The experimenter went through a sample item explaining how the items were scored, ensuring that subjects understood the instructions.

Dependent Measures

Based on the feedback, subjects were asked to estimate for each item (a) what percentage of the other subjects in the experiment also gave the *X* response on that item (consensus information); (b) if they took the whole inventory (rather than just the 12 items selected), on what percentage of the items in that subscale they (or their matched actor) would also give the *X* response (distinctiveness information); and (c) if they (or their matched actor) took the inventory at several different times, what percentage of the time they (or their matched actor) would give the *X* response on that item (consistency information).

Inferences were made on a 9-point scale from 10% to 90% of the people, items, and time for consensus, distinctiveness, and consistency information, respectively. Subjects also rated on a 9-point scale how certain they were about each of their information estimates.

Results

Data Analysis

Information estimates and certainty data were analyzed using a 2 × 2 × 3 × 4 (Sex of Subject × Role × Valence × Category) analysis of variance. Sex of subject was a between-subjects factor; the remaining three independent variables were within-subjects factors. Since actors and observers were yoked, role was considered to be a within-subjects factor, and actor–observer pairs were the units of analysis.

Since more than one dependent measure was obtained, use of multivariate analysis of variance was considered. However, because of the difficulty in interpreting multivariate analysis in which there are repeated measures on more than one factor and multiple levels of the independent variables, univariate analyses were done. An attempt was made to guard against a Type I error by adopting the more stringent Greenhouse–Geisser criterion for rejection of the null hypothesis (Winer, 1971).

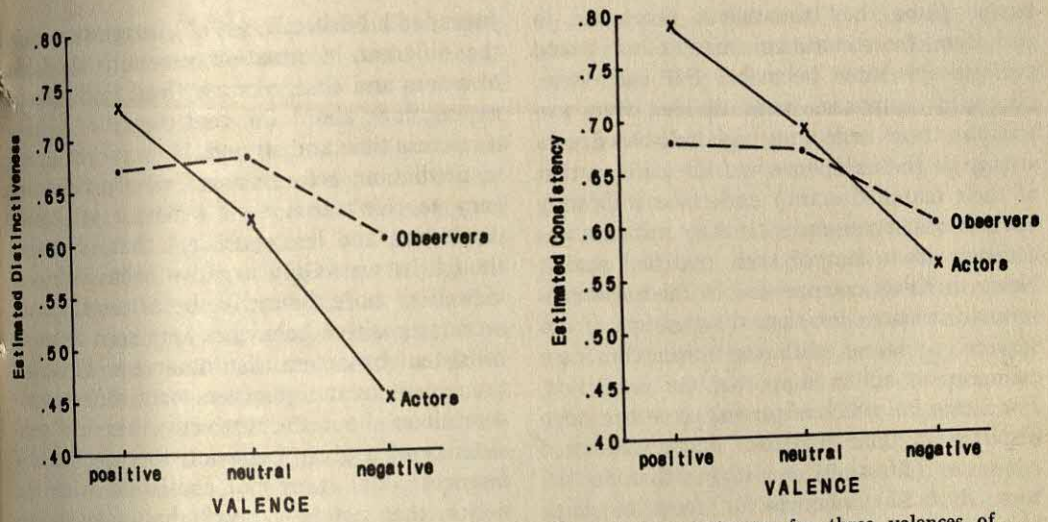

Figure 1. Actors' and observers' distinctiveness and consistency estimates for three valences of behavior. (The higher the number, the lower the estimated distinctiveness.)

All effects reported are either still significant according to this stringent criterion, or if not, an F_{max} test for homogeneity of variance was performed and found to be nonsignificant. Significant three-way or higher order interactions that are not psychologically meaningful are not reported.

Information Estimates

Distinctiveness information. As predicted, actors estimated their responses to be significantly higher in distinctiveness than observers did, $F(1, 16) = 5.48$, $p < .05$. However, a significant Role × Valence interaction, $F(2, 32) = 14.45$, $p < .001$, modified this main effect, indicating that only for negative behaviors did actors infer higher distinctiveness than did observers ($p < .05$; see Figure 1). Actors generated significantly higher distinctiveness for negative than neutral behaviors and significantly lower distinctiveness for positive than neutral behaviors ($ps < .05$). Observers estimated higher distinctiveness for negative than neutral behaviors ($p < .05$), but there was no significant difference in their estimates for positive and neutral behaviors.

A significant main effect of valence was also obtained, $F(2, 32) = 37.34$, $p < .001$. The more positive the response, the lower the estimated distinctiveness.

Consistency information. Contrary to prediction, the main effect of role on consistency estimates did not approach significance. Both actors and observers estimated that consistency of behavior (how often they would give the same response on the same item) would be fairly high (see Figure 1). However, a significant Role × Valence interaction was obtained, $F(2, 32) = 6.71$, $p < .001$. Consistent with the findings for distinctiveness information, actors inferred lower consistency than did observers only for undesirable behaviors, although the difference was not significant. Contrary to prediction, actors estimated significantly higher consistency than did observers for desirable behaviors ($p < .05$). Actors' consistency estimates for positive, neutral, and negative behaviors all differed significantly from each other ($ps < .05$). Observers generated lower consistency for negative than neutral responses ($p < .05$), but there was no difference in their estimates for positive versus neutral responses.

As for distinctiveness inference, a highly significant valence main effect was also found, $F(2, 32) = 32.30$, $p < .001$. Both actors and observers generated highest consistency for positive behaviors and lowest consistency for negative behaviors.

Consensus information. As predicted, observers used their knowledge of their own be-

havior (how they themselves responded to each item) to estimate how many others would perform the same behavior. For each item, observers' responses were divided into two groups—those reflecting high self-based consensus (if their response was the same as that of their matched actor) and those indicating low self-based consensus (if their response was different from that of their matched actor). Newman-Keuls comparisons of the mean consensus estimates for these two groups of observers' responses with the mean consensus estimates of actors supported the prediction. For items on which observers gave the same response as their matched actors, generated consensus ($M = 69$) was higher than for actors ($M = 57$), whereas for items on which observers differed, generated consensus ($M = 52$) was lower than for actors. Each of the means differed significantly from the others ($ps < .01$).

A significant main effect of valence was also found, $F(2, 32) = 12.18$, $p < .01$. The more positive the behavior, the higher the estimated consensus ($M = 65$ for positive, $M = 59$ for neutral, $M = 54$ for negative behaviors). Again, each mean differed significantly from each of the others ($ps < .05$).[1]

Certainty

As predicted, observers having high self-based consensus were significantly more certain than actors of their consensus estimates, $t(18) = 2.27$, $p < .05$. Observers having low self-based consensus were no less certain than actors, $t(18) < 1$. Also as expected, actors were more certain of their distinctiveness and consistency estimates than were observers, $F(1, 16) = 6.20$, $p < .025$, for distinctiveness, and $F(1, 16) = 7.12$, $p < .025$, for consistency.

Significant main effects of valence were also obtained on certainty for each type of information ($ps < .01$). The more positive the behavior, the more certain subjects were of their information estimates.

Discussion

The actor–observer differences in distinctiveness and consistency estimates support Jones and Nisbett's (1972) suggestion that the different information generally available to actors and observers may lead to divergent assumptions about the consistency of behavior across time and stimuli. However, contrary to prediction, actors showed no *general* tendency to think that their behavior was more distinctive and less consistent than observers thought it was. Only negative behaviors were viewed as more distinctive by actors than observers; positive behaviors were seen as more consistent by actors than observers. Thus, although actors and observers made different assumptions about the distinctiveness and consistency of a given behavior, the specific differences found were not consistent with the notion that actors "know" that a given behavior is more distinctive and/or less consistent than an observer thinks it is. Rather, the differences in information inference were primarily determined by desirability of the behavior.

Focusing on causal attributions for positive and negative behaviors, Miller and Ross (1975) and Monson and Snyder (1977) have suggested that actor–observer differences in attribution may derive from informational differences. Actors may attribute "good" behaviors more to themselves because they selectively remember past instances of desirable behavior (Monson & Snyder, 1977). Such selective recall would allow for an actor's inference of high consistency and low distinctiveness for positive acts, and low consistency and high distinctiveness for negative acts. Results of the present study support this notion. Actors generated higher distinctiveness than observers for negative responses and higher consistency than observers for positive responses.

However, the question that comes to mind is, What could be the basis for actors' selective recall? There is no compelling cognitive

---

[1] Significant Valence × Category interactions were also obtained for consensus, distinctiveness, and consistency estimates. They did not appreciably change the implication of the valence main effects, but did suggest that the strength of the valence effect varies somewhat as a function of type of behavior. Similar Valence × Category interactions were also obtained on measures of causal attribution in Experiment 2.

reason for actors to recall desirable behaviors more than undesirable ones. It could be suggested that positive behaviors are perceived as more common by actors than by observers. If this were the case, actors' distinctiveness and consistency estimates might be logical inferences based on perceived frequency of occurrence of the behaviors. (If people are generally helpful, and I give a helpful response, than it would be logical to think that I would usually give a helpful response.) Low distinctiveness and high consistency would be expected for frequently occurring behaviors. The valence main effect for consensus estimates suggests that positive behaviors were indeed seen as most common (highest generated consensus), followed by neutral and negative behaviors, respectively. However, actors did not see positive behaviors as more common than observers did; nor did they see negative acts as more unusual. Thus, the relative frequency of positive behaviors and uniqueness of negative behaviors does not provide an adequate cognitive explanation for the actor–observer differences in distinctiveness and consistency inference.

The failure to find a compelling cognitive explanation for the results suggests that actors' information estimates may be motivationally biased. Sicoly and Ross (1977) recently found evidence for self-serving biases in attribution that could not be explained in nonmotivational terms. The present results suggest that such attribution biases may be traceable to biased estimates of the distinctiveness and consistency of behavior, which are influenced by actors' motivations.

Experiment 2

The purpose of the second experiment was to assess actor–observer differences in causal attribution and to determine whether the discrepancies in information inference found in Experiment 1 influence attributions. The design was identical to that of Experiment 1, with the additional between-subjects factor of information. One group of actors and observers was given the consensus, distinctiveness, and consistency information estimated by actors in Experiment 1. Another group was given the information estimated by observers in Experiment 1. A third group was not given any information. All subjects made causal attributions for their own or their matched actor's behavior. The following predictions were made:

1. Actors given no information would attribute positive behaviors more to internal causes than would observers, and negative behaviors more to external causes than observers would. This prediction was based on the Role × Valence interactions on distinctiveness and consistency estimates found in Experiment 1.

2. Since actors' and observers' informational inferences for neutral behaviors did not differ in Experiment 1, it was predicted that actors' and observers' causal attributions for neutral behaviors would not differ, given no information; nor were they expected to differ in the two information conditions.

3. When provided with identical information, actors' and observers' causal attributions were not expected to differ. Thus, no Role × Valence interactions were expected to occur in the two information conditions. Specifically, (a) actors and observers presented with the information estimated by actors in Experiment 1 would exhibit the strong positivity bias of actors given no information (more internal attribution for positive than negative responses and more external attribution for negative than positive responses); (b) actors and observers given the information generated by observers in Experiment 1 would exhibit the attributional tendencies of observers given no information.

Method

Subjects

Fifty-four male and 54 female undergraduates served as subjects in partial fulfillment of an introductory psychology course requirement. Twenty-seven subjects of each sex were randomly assigned to serve as actors and 27 as observers.

Procedure

The materials and procedure were the same as those used in Experiment 1.

Information Manipulations

Subjects in the information conditions were told that in addition to the feedback regarding their responses, they would be given information dealing with the norms (consensus), validity (distinctiveness), and reliability (consistency) of the inventory items. The information was presented for each item along with the feedback in the following form:

> *Norms*. *X*% of the subjects in this experiment also gave the *Y* response.
> *Validity*. If you/this student took the whole inventory (rather than just these 12 items), you/he/she would give the *Y* response on *X*% of the items in this subscale.
> *Reliability*. If you/this student took the inventory at different times, you/he/she would give the same response on this item *X*% of the time.

Subjects were told that the information was based on past research with the inventory and that they might find it useful in helping them to decide what caused them (or their matched actor) to give a particular response. The actual percentages provided were those generated by subjects in Experiment 1. One actor and one observer were each given the exact consensus, distinctiveness, and consistency estimates generated by one subject in the first experiment. Thus, 18 actors and 18 observers got the information generated by the 18 actors in Experiment 1; 18 actors and 18 observers received the information generated by the 18 observers in Experiment 1. An additional 18 actors and 18 observers received no information.

Dependent Measures

Based on the feedback from the personality–achievement items, subjects were asked to decide what was the most probable cause of each response. The four alternatives provided by McArthur (1972) were presented, as follows:

> 1. Something about me (actors)/this student (observers) probably caused me (actors)/him or her (observers) to give the *Y* response.
> 2. Something about the specific item probably caused me/him/her to give the *Y* response.
> 3. Something about the particular circumstance probably caused me/him/her to give the *Y* response.
> 4. Some combination of 1, 2, and 3 above probably caused me/him/her to give the *Y* response.

Subjects were asked, if they chose Number 4, to specify the particular combination of factors they thought could best explain why they (or their matched actor) gave the *Y* response.

Results

Data Analysis

The design of this experiment was identical to that of Experiment 1, with the additional between-subjects factor of information. Three levels of information were varied: (a) information generated by actors in Experiment 1; (b) no information; and (c) information generated by observers in Experiment 1.

A 3 × 5 (Item Order × Locus of Attribution) chi-square performed on the 1,296 forced-choice attributions was not significant. Therefore, all further analyses were done without regard to item order. Analyses of variance were performed on internal (person) and external (stimulus and circumstance attribution.[2] (The measure of external attribution was derived from summing stimulus, circumstance, and stimulus–circumstance attributions.)

Causal Attribution Effects

Internal attribution. It was predicted that actors given no information would exhibit a "positivity" bias in causal attribution for positive and negative behaviors that would be reduced or eliminated when they were provided with the information generated by observers. Observers' attributions were not expected to reflect as strong (if any) a bias, given no information, but were expected to be biased when given the information generated by actors. To test these predictions, the simple interactions were computed for each level of information. The results supported the predictions. When subjects were given no information, a significant Role × Valence interaction, $F(2, 96) = 10.09$, $p < .001$, revealed that actors made more internal attributions for positive responses and fewer internal attributions for negative responses than observers did, although only the latter difference was significant ($p < .05$). Newman-Keuls tests revealed that actors made significantly fewer internal attributions for negative than for neutral or positive responses ($ps < .05$), whereas ob-

[2] Analyses done on person–stimulus and other internal–external combination attributions are not reported because they are not directly relevant to the hypotheses.

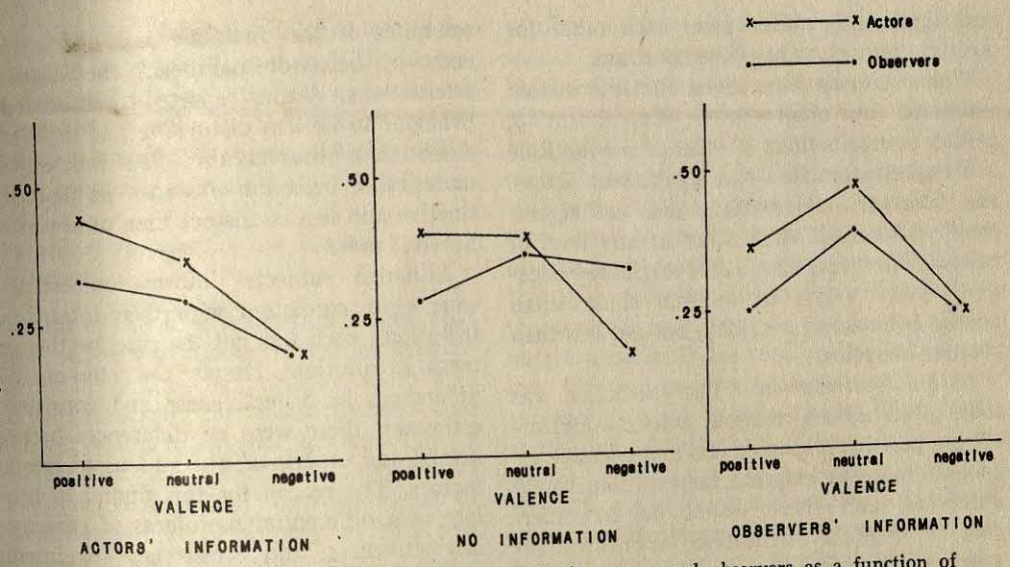

Figure 2. The proportion of internal attributions made by actors and observers as a function of information and behavioral valence.

ervers' internal attributions for positive, neural, and negative responses did not significantly differ from each other (see Figure 2). As predicted, there was no actor–observer difference in internal attribution for neutral responses.

When subjects were given the information generated by the actors in Experiment 1, a significant main effect of valence was obtained, $F(2, 96) = 21.06$, $p < .0$[illegible], but the Role × Valence interaction did not approach significance. As shown in Figure 2, actors' attributions reflected the same pattern as when given no information; the pattern for observers was similar to that of actors. Both groups exhibited the "positivity" bias shown only by actors in the no-information condition. Actors' and observers' attributions did

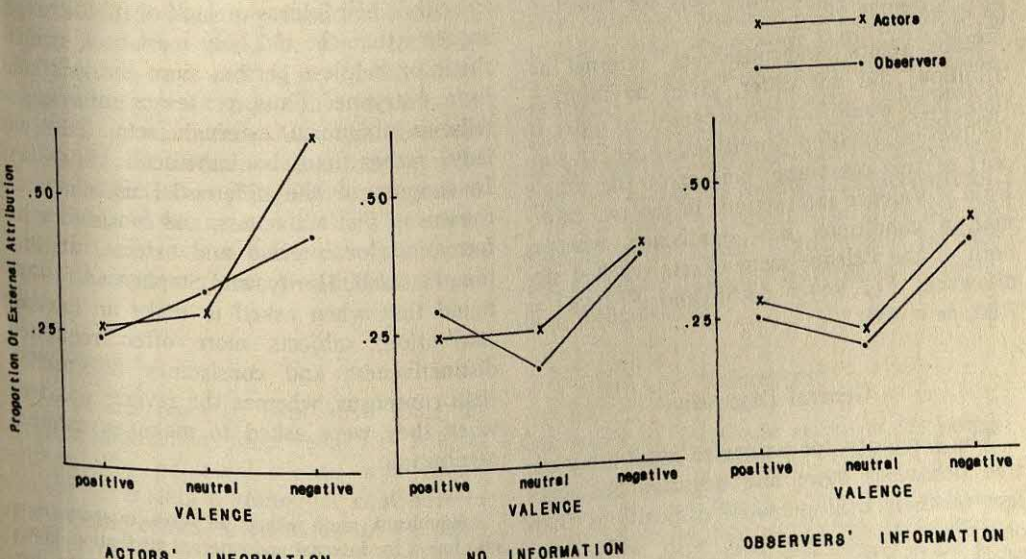

Figure 3. The proportion of external attributions made by actors and observers as a function of information and behavioral valence.

not significantly differ from each other for positive, neutral, or negative behaviors.

When subjects were given the information generated by observers in Experiment 1, neither the main effect of valence nor the Role × Valence interaction was significant. Actors' and observers' attributions did not significantly differ from each other at any level of valence. However, actors still attributed negative behaviors less to internal causes than neutral behaviors ($p < .05$), but not less than positive behaviors.

External attribution. The prediction was that, given no information, actors would attribute positive responses less and negative responses more to external factors than would observers, and there would be no difference in external attribution for neutral responses. As predicted, actors' and observers' external attribution for neutral behaviors did not differ. However, contrary to prediction, there were no actor–observer differences for positive or negative responses either (see Figure 3). The simple Role × Valence interaction for the no-information condition was not significant. However, the simple main effect of valence was significant, $F(2, 96) = 7.21$, $p < .001$, indicating that both actors and observers attributed negative responses more externally than neutral responses, although the difference was significantly only for observers ($p < .05$).

Since actors' and observers' external attributions did not differ, given no information, they would not be expected to differ in the two information conditions either. In support of this reasoning, neither of the simple Role × Valence interactions in the two information conditions was significant, whereas both of the valence main effects reached significance, $F(2, 96) = 33.65$ and $F(2, 96) = 7.80$, ps $< .001$.[3]

General Discussion

The tendency for actors to attribute positive behaviors more and negative behaviors less to their own personal dispositions than observers do is consistent with self-serving biases found in previous research (Bradley, 1978). Furthermore, actors' and observers' estimates of the distinctiveness and consistency of behavior paralleled the disparate attributions. Actors reported their desirable behavior to be less distinctive and more consistent than observers thought it was, whereas undesirable behavior was seen as more distinctive and less consistent than observers believed it to be.

Although subjects' information estimates were quite consistent with their internal attributions, such was not the case for their external attributions. Despite the actor–observer differences in disinctiveness and consistency estimates, there were no differences between actors' and observers' attributions to external factors. The reason for this finding may relate to a differential usefulness of consensus, distinctiveness, and consistency for internal versus external attribution. It has been suggested that distinctiveness and consistency information are more relevant for internal than external attribution because they provide clues as to what sort of person someone is (Anderson, 1974; McArthur, 1976). If we know that Priscilla usually helps the old lady (high consistency) and that she helps out other people, too (low distinctiveness), we can infer that she is a helpful person. In contrast, knowing that other people help the old lady (high consensus) has no direct implications about Priscilla's helpfulness or lack of it. Rather, it suggests that the old lady must be a sympathetic or helpless person, since she gets help from everyone. Thus, consensus information tells us about an external factor (the old lady) rather than about the actor (Priscilla). In support of the differential usefulness of consensus, distinctiveness, and consistency information for internal and external attribution, Garland, Hardy, and Stephenson (1975) found that when asked to make an internal attribution, subjects more often requested distinctiveness and consistency information than consensus, whereas the reverse was true when they were asked to make an external attribution.

---

[3] Significant main effects of verb category were also found for internal and external attribution. However, since no actor–observer differences were predicted or found, the findings pertaining to verb category are not reported.

If consensus information is most useful for making an external attribution, then actors' and observers' external attributions would not be expected to differ in the present experiment, since actors and observers did not differ in their consensus estimates.

Influence of Information on Causal Attribution

Results of the present research suggest that actors' self-serving biases in causal attribution can be reduced by providing them with information about the distinctiveness and consistency of their behavior, generated by an observer. Such information may be viewed as more objective than their own knowledge of distinctiveness and consistency of their behavior, which, like their attributions, appears to reflect self-serving biases. Similarly, observers can be swayed by actors' biased information estimates to attribute positive behavior more and negative behavior less to an actor's personal disposition.

It has been suggested that self-serving biases reflect strategic self-presentation by actors, rather than their private beliefs (Bradley, 1978). Attempts should be made to minimize the likelihood that such an artifact may be responsible for experimental findings. In the present research, subjects were told that their responses to the inventory items and the dependent measures would be kept confidential. No names appeared on any of the forms, and only the experimenter could identify the completed questionnaires. Although observers were shown the inventory-item responses of another subject, that person was not present at the time and was never identified by name. Thus, the influence of self-presentation motives in the present research should have been minimal.

Implications

The results reported here have some interesting implications for a variety of natural settings. The perennial dieter, who claims that he never eats a thing yet continues to gain weight, comes to mind as an example. He may attribute his obesity to an abnormally slow metabolism or some other factor that is out of his control. In accord with his attribution, he reports that he hardly ever snacks between meals—that is, snacking is highly distinctive and inconsistent. On the other hand, the dieter's wife, who attributes her husband's obesity to his eating habits, correctly reports the late afternoon chocolate bars and midnight refrigerator raids. If the dieter were to keep a running record of every bite he took during the day, he would have the more objective information reported by the observer and might be convinced that his weight problem is the result of his excess eating. This self-monitoring technique has been successfully used to help dieters in correctly attributing causality and, ultimately, in losing weight (Mahoney, 1974). Similar methods might be useful in other therapeutic or educational settings where taking responsibility for negative behaviors is a prerequisite for positive change.

On the other hand, there are also situations in which the actor's information may be more accurate or complete than the observer's. A student may attribute his or her lack of attendance in Psychology 101 to the fact that the lectures are boring and uninformative. Consistent with this attribution, that student may know that his or her attendance at other classes is and always has been excellent. The professor may attribute the student's behavior to an unreliable nature, based on consistent absence throughout the semester, regardless of what topics were being covered. In this situation, the actor (student) has more consistency and distinctiveness information than the observer. If the professor learned that the student's behavior in Psychology 101 really was highly distinctive and inconsistent, he or she might be expected to alter the impression of the absent student and perhaps even to realize that the lectures leave something to be desired.

Sex Differences in Eavesdropping on Nonverbal Cues

Robert Rosenthal and Bella M. DePaulo
Harvard University

Three series of studies investigated the hypothesis that nonverbally, women are more interpersonally accommodating than men. The first series of studies showed that women lost much of their advantage in decoding visual cues when the cues were based on displays too brief to be under good sender control. The second series of studies showed that as nonverbal cues became less intended (more "leaky"), women showed decreasing advantage over men in accuracy of decoding nonverbal cues. There was also a trend for women who were more skilled at eavesdropping on nonverbal cues to be seen as having less successful social outcomes. Women were also more biased to use (the more controllable) visual cues than tone of voice cues and especially so when the video cues were of the face rather than of the "leakier" body. The third series of studies showed that women were more polite in their ascription of characteristics to others, more accurate in decoding of nondeceptive behavior, but substantially more likely to interpret deceptive cues as the deceiver wanted them to be interpreted. Finally, it was shown that women's nonverbal cues were more easily read than men's.

The superiority of women over men in the accuracy of decoding nonverbal cues has long been postulated and investigated. Recently, these investigations have been exhaustively, systematically, and quantitatively summarized so that the issue is no longer in doubt; women are indeed superior to men in the decoding of nonverbal cues (Hall, 1978).

Also based on the results of dozens of studies of sensitivity to nonverbal cues is the general finding that people who are more skillful at decoding nonverbal cues are more effective in their interpersonal relationships (Hall, Rosenthal, Archer, DiMatteo, & Rogers, 1978; Rosenthal, Hall, Archer, DiMatteo, & Rogers, 1979; Rosenthal, Hall, DiMatteo, Rogers, & Archer, 1979). Given that women in our culture have traditionally played more expressive, socioemotional, and supportive rather than instrumental roles (Parsons, 1955; Parsons, Bales, & Shils, 1953; Zelditch, 1955), their superiority at decoding nonverbal cues, a concomitant of superior interpersonal relationships, seems quite consistent.

Recently, however, a question has been raised about the conditions under which skill at decoding nonverbal cues might actually be detrimental to smooth social functioning (Rosenthal, Hall, DiMatteo, Rogers, & Archer, 1979). The evidence suggests that social relationships may suffer when people are too good at decoding nonverbal messages they were not intended to receive. Thus, for example, people who are very good decoders of very briefly exposed (e.g., 42 msec) facial and body cues may have less satisfactory interpersonal relationships (Rosenthal, Hall, DiMatteo, Rogers, & Archer, 1979).

We thank Faye Crosby, Michael Fridkin, Carolyn Rieder Green, Judith A. Hall, Judith Rosenkrantz, Shelley Taylor, and Miron Zuckerman for their helpful comments on an earlier draft of this manuscript.

If it is disruptive of smooth interpersonal functioning for a participant to "know too much" about the state of the other, we would expect women to show relatively less advantage over men in decoding nonverbal cues when those cues are under less control of the sender and are more likely to be unintended than intended cues. The plausibility of this hypothesis is strengthened by Weitz's (1976) finding that the nonverbal styles of females are closely adjusted to the personality traits of male partners.

Among the various channels of nonverbal communication that have been studied, the most informative, and also the one most likely to be best controlled by the sender, is the face (Ekman & Friesen, 1969; Izard, 1971; Rosenthal, Hall, DiMatteo, Rogers, & Archer, 1979). Compared to the face, each of the following sources of nonverbal cues is likely to be less informative under ordinary circumstances of interaction and less likely to be as controllable by the sender:

1. *Body.* Ekman and Friesen (1969, 1974) have shown that the body is more likely than the face to give off or "leak" deception cues.

2. *Tone of voice.* Several studies (Ekman, Friesen, & Scherer, 1976; Streeter, Krauss, Geller, Olson, & Apple, 1977; Krauss, Geller, & Olson, Note 1) have shown that tone of voice is an additional source of cues to deception or stress. It has also been shown that tone of voice may leak one's true feelings about oneself (Bugental, Henker, & Whalen, 1976; Bugental & Love, 1975; Holzman & Rousey, 1966) or about others (Weitz, 1972).

3. *Very brief exposures.* Very brief exposures to face or body cues appear likely to offer further unintended cues to the other's state without being as controllable as cues (in the same channels) occurring in longer time frames (e.g., 42 msec vs. 2,000 msec) (Ekman & Friesen, 1969; Rosenthal, Hall, DiMatteo, Rogers, & Archer, 1979).

4. *Discrepancy.* Except in the special cases of irony, sarcasm, or humor, discrepancies between visual and auditory nonverbal cues may be unintended and difficult to control (DePaulo, Rosenthal, Eisenstat, Rogers, & Finkelstein, 1978).

The purpose of the present series of studies was to investigate the hypothesis that nonverbally, women are interpersonally more accommodating than are men. We wanted to know whether women's greater social civility would be evident in their decoding skills, in their attentional biases, in their interpretive biases, and in their nonverbal expressiveness. More specifically we wanted to know the following:

1. Do women show relatively less advantage over men in their decoding accuracy as the nonverbal cues decoded become less intended and less controllable by the sender (i.e., are women less likely to eavesdrop on the leakages of others, taking into account women's general superiority at decoding nonverbal cues)?

2. Do women, more than men, attend preferentially to the more overt and more controlled nonverbal channels?

3. Do women, more than men, ascribe socially more desirable characteristics to the nonverbal cues they read?

4. Do women, more than men, interpret nonverbal cues in ways in which the sender would like them to be interpreted?

5. Do women, more than men, permit their nonverbal cues to be read by others?

6. Given the degree of sex role stereotyping that still exists, are there social costs to women who are less interpersonally accommodating in these nonverbal ways?

Study Series 1

Very Brief Exposures

A series of 10 studies was conducted to test the hypothesis that for visual cues of very brief exposure, women's advantage over men in accuracy of decoding would be smaller than that established for visual cues available in longer time frames (Hall, 1978).

Method

The Brief Exposure Profile of Nonverbal Sensitivity (PONS), a test of sensitivity to nonverbal visual cues with median exposure lengths of only 250 msec (Rosenthal, Hall, DiMatteo, Rogers, & Archer, 1979), was administered to six samples of college students ($N = 352$), three samples of adults ($N = 87$), and one sample of high school students ($N = 111$). For each of the 10 samples, the magnitude of females' superiority was computed by subtracting

the mean accuracy of the males from the mean accuracy of the females and dividing the difference by the common standard deviation of the male and female subsamples (Cohen, 1977; Rosenthal & Rosnow, 1975). An analysis of variance showed that the three types of samples (college, adult, and high school) did not differ in the degree to which the females outperformed the males, $F(2, 7) < 1$; accordingly, all subsequent analyses disregarded the age level of the samples.

Results

Table 1 shows the stem-and-leaf plot (Rosenthal & Rosnow, 1975; Tukey, 1977) of our results side by side with the stem-and-leaf plot of the results of the 29 studies reported by Hall (1978), in which she computed the magnitude of female superiority in sensitivity to visual cues exposed for at least several seconds, on the average.[1] The most obvious difference between the two distributions is the percentage of studies of ordinary-length visual cues in which women showed larger advantages over men (41%) than was true in any study of high-speed cues. In contrast, the percentage of studies of ordinary cues in which women showed smaller advantages over men than was true in any study of high-

[1] Tukey (1977) developed the stem-and-leaf plot as a special form of frequency distribution to facilitate the inspection of a batch of data. Each number in the data batch is made up of one stem and one leaf, but each stem may serve several leaves. Thus, the fifth stem of Table 1, a .5, is followed by two leaves of 3 and 4 representing the two numbers .53 and .54. The first digit is the stem; the second is the leaf. The eye takes in a stem-and-leaf plot as it does any other frequency distribution, but the original data are preserved with greater precision in a stem-and-leaf plot than would be the case with ordinary frequency distributions.

speed cues was only 7%, a difference that was significant at $p = .006$ (sign test) or at $p = .08$ by the less focused Kolmogorov-Smirnov test, $\chi^2(2) = 5.09$. The summaries of the two distributions given at the bottom of Table 1 show that the two variances differ substantially, $F(28, 9) = 6.00$, $p = .008$, with the bulk of this heterogeneity due to the studies of ordinary nonverbal cues showing very large advantages of females over males.

In summary, 10 studies of sex differences in accuracy of judgments of briefly exposed cues showed that women were markedly less advantaged at this task than they were at reading visual cues of ordinary duration. These results suggest that women may be more polite than men in their decoding of nonverbal cues (i.e., refraining from decoding too efficiently those nonverbal cues under less control of the encoder).

Study Series 2

Ordered Leakage Channels

Method

Five measures of sensitivity to nonverbal cues derived from the PONS were administered to samples of 148 high school students and 94 college students. Details of the first four measures are given in Rosenthal, Hall, DiMatteo, Rogers, and Archer (1979), and details of the fifth measure are given in DePaulo et al. (1978). (See Appendix.) Briefly, the measures were as follows:

1. *Face.* A 20-item test of sensitivity to facial expressions.
2. *Body.* A 20-item test of sensitivity to body movements.
3. *Tone.* A 40-item test of sensitivity to speech masked by content-filtering (Rogers, Scherer, & Rosenthal, 1971) and random-splicing techniques (Scherer, 1971).
4. *Brief exposures.* A 40-item test of sensitivity to high-speed exposures of the face or of the body with a median exposure length of only 250 msec.
5. *Discrepancies.* A 128-item test of sensitivity to the degree of discrepancy between the tone of voice and either facial expressions or body movements.

The five measures are listed in the order in which we believed them to fall on a dimension of "leakiness." Thus, the face cues were felt to be the best controlled or least "leaky," whereas discrepancy cues were felt to be least well controlled or most "leaky." Ekman and Friesen's (1969, 1974) work convinces us that the body may be a leakage channel, though Feldman (1976) suggests that this may not always be the case. Evidence for the leakiness of tone-of-voice cues is more pervasive (deriving from studies of personality, psychopathology, and attitudes, as well as from studies of deception) and is as yet uncontested. Briefly exposed cues may be similar to the "microaffect displays" discussed by Ekman and Friesen (1969). These microdisplays may be mere fragments of full displays, or they may be complete movements that are greatly reduced in time. In either case, they should be more difficult to control than any of the full-channel messages communicated at ordinary speeds. Finally, we believe that discrepant messages would be most "leaky" or difficult to control because (a) they involve simultaneous communication by two different channels, each of which might itself be difficult to control, and (b) the combined effect of both messages together might add a further element of subtlety or uncontrollability.

The specific ordering of these five measures was necessarily highly speculative, since prior studies had rarely ever compared more than two of these channels simultaneously. However, it should be noted that given only the placement of our most and least leaky channels (face and dicrepancies), our particular ordering of the five measures (with linear contrast weights of +2, +1, 0, −1, −2) correlated very highly ($r = .89$) with the ordering that does not make any discrimination among the middle three measures (with contrast weights of +1, 0, 0, 0, −1). Or, even more conservatively, if we had merely claimed that the face was less leaky than any of the other channels, the resulting ordering (+4, −1, −1, −1, −1) would still correlate very highly ($r = .71$) with the present ordering.

Results

Table 2 shows the mean intercorrelations among the five measures for the two samples. The fact that all correlations were positive, most of them significantly so, shows that these measures were clearly related to each other, but not to as great an extent as we would expect if all the measures were tapping only a single underlying skill. The diagonal of the matrix of Table 2 shows the internal consistency reliability for each of the measures. The median reliability of .40 was substantially greater than the median intercorrelation (.22) among the five measures, supporting the relative independence of the five measures.

The bottom row of Table 2 shows the degree of accuracy exceeding chance (in z units) for each of the five measures. As we would expect, the channels posited as more leaky or less controllable tended to be less accurately decoded, $r(3) = .87$, $p < .03$, one-tailed. However, even the most difficult cu

Table 2
Intercorrelations, Reliabilities, and Accuracy Levels of Five Measures of Sensitivity to Nonverbal Cues

Measure	Face	Body	Tone	Brief exposures	Discrepancies
Face	**.40**				
Body	.21*	**.36**			
Tone	.30***	.08	**.28**		
Brief exposures	.40***	.33***	.27**	**.53**

Accuracy (in σ units)	3.88	2.82	1.82	2.58	1.12

Note. Internal consistency reliabilities are in boldface type in the diagonal. Accuracy is defined by the degree to which performance exceeds chance (in σ units).
* $p \leq .05$.
** $p \leq .01$.
*** $p \leq .001$.

to decode, those of discrepancy, were decoded very much better than chance (1.12σ). Inspection of the reliabilities of the five measures also shows that differences in reliability could not be responsible for differences in accuracy. The most reliable measure was also the one with the lowest accuracy, and the overall correlation between test accuracy and reliability was negative, $r(3) = -.33$, *ns*.

Table 3 shows the results of our analysis for each sample and for both combined. The magnitude of females' superiority over males in decoding decreased in a linear manner, going from less to more leaky channels. Based on the analyses of variance testing the Sex × Linear Trend interaction, the college sample showed the regression ($r = .96$) to a significant degree, the high school sample showed the regression ($r = .72$), but not to a significant degree, and the combined samples showed the regression ($r = .91$) to a significant degree ($p = .004$). As channels became more and more leaky, females lost more and more of their advantage. These results, too, suggest that women may be more polite in their decoding of nonverbal cues (i.e., refraining more

Unweighted *M*	.17		.27	.20
Weighted *M*	.16		.27	.19

Note. Loss of female superiority was defined as the difference between female superiority in the face channel (in σ units) and female superiority in each of the leakier channels (in σ units).

and more from decoding effectively those nonverbal cues that are less and less controllable by the encoder).

Additional Evidence

Although we knew of no other studies in which sex differences in sensitivity to nonverbal cues had been specifically examined for a series of channels differing in leakiness, we tried to find studies in which at least one relatively leaky channel could be compared to the least leaky channel, the face, with exposure length not too brief.

We found 2 studies in which female superiority had been measured on the body channels using the same test as employed in the present article (Rosenthal, Hall, DiMatteo, Rogers, & Archer, 1979, chapters 6 and 8); 10 studies in which female superiority had been measured in the tone-of-voice channel (Hall, 1978); 10 studies in which female superiority had been measured for brief-exposure visual cues (the present article); and 1 study in which female superiority had been measured for discrepant cues (DePaulo et al., 1978). In the 2 studies measuring female superiority in the body channel, female superiority in the face channel was measured for the same sample. In all other cases, female superiority in the face channel was defined by Hall's visual category data (mean effect size = .32σ).

Table 4 shows the loss (in σ units) of female superiority in going from the face channel to each of the four more leaky channels. Just as was the case for our two samples of Table 3, the earlier studies yielded an ordering of loss of female superiority that went from face to body to tone to brief exposure to discrepant cues. When these earlier studies were combined with our two studies, the degree of linear relationship between the ordering of leakiness of channel and the loss of female superiority was very great, $r(3) = .99$, $p < .001$.

Social Consequences of Eavesdropping

Teacher Ratings

Method. To obtain an indication of whether eavesdropping skill might have social consequences, and more particularly to see whether females might be penalized for being too accurate at reading hidden cues, we examined teachers' ratings of the social effectiveness of the high school students who had been administered the five measures described earlier. Several teachers ($M = 2.4$, range = 1–5) rated the students whom they knew on their popularity with the same sex, popularity with the opposite sex, and degree of social understanding. We correlated all three ratings with degree of skill in each of the five nonverbal tasks, separately for males and females, yielding a total of 30 correlations. Because the patterns of results for the three ratings were so similar (the intercorrelations among the three variables were .69, .79, and .90), we averaged the correlations obtained from the three ratings to yield the summary correlations of Table 5.

Results. Table 5 shows a strong trend, though not a significant one, for social effectiveness to be less and less strongly related to nonverbal sensitivity as we move from less to

Table 5
Correlations Between Sensitivity to Five Types of Nonverbal Cues and Teachers' Ratings of Social Effectiveness

Decoding skill	Males (n = 43)	Females (n = 63)	Difference	M
Face	.36*	.38**	−.02	.37***
Body	.10	.03	.07	.07
Tone	.42**	.23	.19	.33***
Brief exposures	.33*	.16	.17	.25**
Discrepancies	.03[a]	−.06[b]	.09	−.02
Correlation (n = 5) between magnitude of relationship and degree of "leakiness" of channel	−.40	−.69	.60	−.56

Note. ns vary from row to row; median ns are given at head of columns.
[a] The analogous value for a sample of 36 junior high school males was .18.
[b] The analogous value for a sample of 37 junior high school females was −.12.
* $p \leq .05$.
** $p \leq .01$.
*** $p \leq .001$.

more "leaky" channels. This trend was found for both males (r = −.40) and females (r = −.69), but the trend was stronger for females, as shown in the third column of Table 5. Relative to males, correlations between social effectiveness and nonverbal sensitivity dropped off more linearly for females in going to more leaky channels (r = .60). There are indications, therefore (and that is all they are), that eavesdropping skill may not be as socially beneficial as skill at decoding less "leaky" channels. These indications are stronger for females than for males, although we should note that even for females, the average correlation still tends to be positive rather than negative.

Self-Ratings

Method. For both the high school and college samples described earlier, we obtained students' self-ratings of the quality of their relationships with members of their own and of the opposite sex. These ratings were correlated with skill at decoding each of the five types of nonverbal cues, separately for males and females. Because the results for the ratings of same- and opposite-sex relationships were similar, we present the average of the correlations of each rating with each skill in Table 6, separately for the males and females of the two samples.

Table 6
Correlations Between Sensitivity to Five Types of Nonverbal Cues and Self-Ratings of Social Relationships

Decoding skill	High school		College	
	Males (n = 36)	Females (n = 43)	Males (n = 32)	Females (n = 49)
Face	.14	−.13	.09	−.09
Body	−.05	−.15	.22	.18
Tone	.03	−.04	−.23	−.18
Brief exposures	.06	−.17	.12	−.23
Discrepancies	.29	.03	−.03	.06
Correlation (n = 5) between magnitude of relationships and degree of "leakiness" of channel	.50	.56	−.31	−.10

Note. ns vary from row to row; median ns are given at head of columns.

Table 7
Correlations Between Sensitivity to Five Types of Nonverbal Cues and Bias Favoring Positive Affect

Decoding skill	High school		College		
	Males (n = 46)	Females (n = 63)	Males (n = 32)	Females (n = 50)	Interaction[a]
Face	.02	.09	.14	−.12	.33
Body	−.09	.19	−.03	−.20	.45
Tone	−.01	−.14	.12	−.15	.14
Brief exposures	−.03	.12	.22	−.04	.41
Discrepancies	−.17	.11	.01	−.33	.62
Correlation (n = 5) between magnitude of relationship and degree of "leakiness" of channel	−.67	−.04	−.02	−.38	

Note. ns vary from row to row; median ns are given at head of columns.
[a] The difference between the correlations on the diagonals of the 2 × 2 table formed from the factors gender and age, for example, [(.09) + (.14)] − [(.02) + (−.12)] = .33.

Results. Table 6 shows that self-ratings of the quality of relationships with others were not strongly related to sensitivity to nonverbal cues (median r = .00), a finding that is consistent with the results of 10 earlier studies (median r = .06; Hall et al., 1978).

The last row of Table 6 provides an interesting hypothesis for future testing. Among high school males and females, there is a tendency (rs = .50 and .56, respectively) for correlations between nonverbal skill and self-ratings to grow larger as channels increase in leakiness. Thus, for our younger students, skill at eavesdropping on increasingly leaky channels was associated with increasingly better social relationships, as *they* perceived these relationships. These results are exactly opposite to those obtained when teacher ratings had been employed as the criteria of social effectiveness (rs = −.40 and −.69 for males and females, respectively).

When we examine the analogous results for the college males and females of Table 6, we find the trend to be reversed. For our older students, skill at eavesdropping on increasingly leaky channels was associated with increasingly poor social relationships, as they perceived these relationships. Perhaps these students have learned, as have the younger students' teachers, that it may not be beneficial to social relationships to be an effective eavesdropper on leaked nonverbal cues. It may well be that this knowledge is tacit rather than explicit (Polanyi, 1962).

Biases and Nonverbal Skill

The Nonverbal Discrepancy Test (DePaulo et al., 1978), in which conflicting visual and auditory cues are presented, provides several measures other than accuracy at decoding discrepant cues. Two of these measures are indexes of bias in the processing of nonverbal cues. One of these biases, the positivity bias, is the extent to which the subject is more influenced by positive than by negative nonverbal cues. Thus, when either video or audio positive cues are paired with negative cues in the remaining channel, the positivity-biased subject rates the scenario as more positive. These bias scores are corrected for the tendency to rate all scenarios as positive by subtracting ratings of positiveness made to scenarios showing no discrepancy of affect between channels. The other bias, video bias, is the extent to which the subject is more influenced by video than by audio nonverbal cues.

Positivity Bias

Table 7 shows the correlations between subjects' degree of positivity bias and their skill at decoding five types of nonverbal cues. Results are given separately for the male and

female subjects of the high school and college samples we have been discussing.

For male subjects, there is a tendency for these correlations to be more positive at the college level than at the high school level, whereas for the female subjects, there is a tendency for these correlations to be more negative at the college than at the high school level; for interaction of Sex × Sample, $F(1, 2) = 11.85$, $p < .08$. One interpretation of these results is that relative to men, as women mature, those who tend to focus more on the "good" in nonverbal cues tend to become less accurate decoders of nonverbal cues, perhaps in an effort to avoid knowing "more than they should" about others' states. If this interpretation were reasonable, we might expect to find that the interaction described would be especially true for skills of decoding the less controllable, more leaky channels. The statistical test for the systematic growth of a two-way interaction along an ordered dimension is the A × B × Linear Trend in C interaction, which for these data was the interaction of Sex × Sample × Linear Trend in Leakiness of the Nonverbal Skills. Results of this analysis supported our interpretation, $F(1, 3) = 18.25$, $p < .03$. That is, the tendency for women, relative to men, to become less accurate at nonverbal decoding as they mature, when they are more inclined to see the "good" in nonverbal cues, becomes systematically greater when skill at nonverbal decoding would make them more able and likely to eavesdrop.

Video Bias

When people are confronted with contradictory nonverbal cues in the video and audio channels, there is a general tendency for them to be more influenced by the video than the audio cues (DePaulo et al., 1978). People show interesting individual differences, however, in the degree to which they are biased in favor of video cues.

One concomitant of a greater video bias may be the tendency to focus more on intended rather than on leaked nonverbal cues, since video bias is most pronounced for facial cues, and facial cues are felt to be best controlled and least leaky. As we might expect from the other results presented in this article, we found females to be more biased in favor of video nonverbal cues in both the high school and the college samples (mean effect size for sex difference = $.55\sigma$; $df = 161$; $p < .001$). We also found that this sex difference in video bias was significantly greater when the video cues were from the face rather than from the body (mean effect size for Sex × Channel interaction = $.37\sigma$; $df = 161$; $p = .02$).

These results are consistent with the interpretation that women, more than men, are more likely to attend to better controlled rather than to more leaky channels of nonverbal communication. Still greater force is given to this interpretation by the finding of a trend for this sex difference in video bias to be greater when self-reported relationships with the opposite sex were above average in quality (effect size = $.20\sigma$; $df = 161$; $p < .16$). Perhaps women are reinforced with better opposite-sex relationships when they attend to the better controlled channels and learn to avoid eavesdropping on the more poorly controlled, more leaky channels.

Study Series 3

Perception of Others

In a third series of studies, 20 male and 20 female college students were videotaped while describing a person they liked, one they disliked, one they were ambivalent about, one they were indifferent to, a person they really liked as though they disliked him or her, and a person they really disliked as though they liked him or her. The first two encodings were of clear affects, the second two encodings were of mixed affects, and the third two encodings were of deceptive affects. Each of the 40 encoders also served as decoder and rated the sendings of 20 of the encoders on the degree to which the sending reflected liking, disliking, ambivalence, discrepancy, tension, and deception.

There were large overall differences in the average ratings assigned to encodings by decoders. Perhaps as part of the pattern of seeing only what one is supposed to see, females rated all encodings as significantly less tense

(effect size = 1.45σ; $t = 4.10$, $p < .001$), significantly less ambivalent (effect size = 1.48σ, $t = 4.19$, $p < .001$), and significantly less discrepant (effect size = 0.84σ; $t = 2.38$, $p < .02$) than did males. There were no sex differences in ratings on the other three scales ($t < 1$).

Overlooking Deception

Each decoder's ratings could be scored for accuracy of decoding. For example, a decoder was scored as more accurate in decoding liking sendings if higher liking ratings were made to the encodings of liking than to the encodings of disliking. For both the liking and disliking accuracy variables, women were substantially and significantly more accurate than men, with effect sizes of $.92\sigma$ ($p < .001$) for liking and $.68\sigma$ ($p < .001$) for disliking. Thus, at this task, as at so many others, women were more accurate than men at decoding nonverbal cues.

A result of greater interest, however, was that compared to men, women were substantially and significantly more likely to interpret the deceptive encodings as the deceiver wanted them interpreted rather than as the deceiver really felt. That is, when senders were describing the person they liked as though they disliked him or her, females were more likely than males to believe that the sender was communicating disliking; analogously, women were more likely to interpret "dislike as though like" descriptions as communications of liking. Effect sizes were $.78\sigma$ ($p < .001$) for liked as though disliked and $.95\sigma$ ($p < .001$) for disliked as though liked descriptions. In decoding deception, then, women are more likely politely to "read" what they are supposed to read rather than what is true.

Openness in Sending

There is considerable evidence to suggest that women are better encoders than men (Hall, Note 2), and the suggestion has been offered that women have been encouraged to be more emotionally expressive than men (Buck, Miller, & Caul, 1974; Buck, Savin, Miller, & Caul, 1972). One way to view these results, in the context of the present article, is that women not only eavesdrop less than men but that they are also more interpersonally accommodating by making themselves easy to read nonverbally.

In the present person description study, as in the studies reviewed by Hall (Note 2), we found that the nonverbal messages communicated by women were more easily decoded than the nonverbal expressions of men (effect size = $.73\sigma$, $p < .05$).

If women more than men allowed their nonverbal behaviors to be conveniently legible, we might also expect to find a sex difference on Snyder's Self-Monitoring Scale (1974). Persons who score high on this scale are thought to be more controlling of the cues they emit, whereas those who score low are thought much more to "wear their feelings on their sleeves." We administered the Self-Monitoring Scale to 37 males and 44 females of the high school sample discussed in Study Series 2 and to the 20 males and 20 females in the person description study. The sex differences in self-monitoring for these two samples, though modest in size ($.42\sigma$ and $.25\sigma$) were consistent with each other and with our expectations: Women, more than men, were likely to express their true feelings rather than to control or monitor their nonverbal expressions to fit a given situation (mean effect size = $.34\sigma$; combined $p = .03$).

Conclusions

Three series of studies were conducted that addressed the hypothesis that nonverbally, women will be more interpersonally accommodating than will men. The first two series of studies focused on the hypothesis that as nonverbal cues become less intended and less controllable by senders, women will show relatively less advantage over men in their decoding accuracy. Put another way, the hypothesis was that women would be relatively less likely than men to eavesdrop on the nonverbal leakages of others, correcting for women's general superiority at decoding nonverbal cues.

The first series of studies, based on 10 samples, showed that women's general ad-

vantage over men in decoding visual cues was to a large extent lost when the visual cues were of very brief duration (median duration of 250 msec). Exposures so short may be less controllable by the sender and may carry more unintended or leaked messages than exposures in longer time frames.

The second series of studies, based on two samples (and 23 earlier studies), showed that when five measures of skill in decoding nonverbal cues were arranged from most controllable to least controllable (most leaky), women showed a systematic decrease in their superiority over men in going from the less to the more leaky channels. Although our initial ordering of these five measures of skill on a dimension of leakiness was very tentative, the overall results presented in this article provide good support for the construct validity of this particular ordering of the five measures. Most compelling in this regard are the accuracy results, based on over 20 studies, which show that the initial ordering of these five types of cues fits very well with the ordering of the magnitude of women's loss of superiority in decoding these cues.

This additional evidence for the hypothesis that women were relatively less likely than men to eavesdrop on leaky nonverbal channels was accompanied by suggestive evidence that there may be social costs to eavesdropping. The greater one's skill at decoding the leakier channels, the relatively less effective are one's interpersonal relationships as judged by outside observers—a finding that was stronger for women than for men. This result, and the finding that older students show similar results for self-ratings of interpersonal relationships, however, are based on only two samples and should, therefore, be viewed only as hypotheses for considerable further evaluation.

The second series of studies also suggested that as women mature, those who tend to focus on the positive or "good" in the nonverbal cues of others may tend to become less accurate decoders of nonverbal cues, and more especially so as these nonverbal cues become less intended, less controllable, or more leaky. This series of studies also showed that relative to men, women were more biased to utilize visual cues than tone-of-voice cues, and more so when these cues were of the face rather than of the body. Once again, then, women appeared more likely to use the information from channels under better sender control and offering lower degrees of leakiness. This sex difference in video bias tended to be stronger among those with better opposite-sex relationships.

The third series of studies showed that women rated the behavior of others as less tense, less ambivalent, and less channel discrepant—results that fit well with the pattern of seeing only what it is polite to see. This series also showed that women were markedly superior to men in the decoding of clear, nondeceptive behavior. However, when deception cues were being emitted, women were substantially more likely to interpret these cues as the deceiver wanted them to be interpreted, rather than as the deceiver really felt. Finally, this series of studies suggested not only that women were less likely to eavesdrop on leaky nonverbal channels but also that they were more likely to be accurately decoded by others.

Taking together the results of our three series of studies, it seems reasonable to conclude that women are more polite in the nonverbal aspects of their social interactions than are men. They are more guarded in reading those cues that senders may be trying to hide, but more open in the expression of their own affective states. Further, there are indications that women who are less accommodating in these nonverbal ways experience less successful interpersonal outcomes. Perhaps women in our culture have learned that there may be social hazards to knowing too much about other people's feelings. This relative avoidance of eavesdropping by women is consistent with the standards of politeness and social smoothing-over that are part of the traditional sex role ascribed to women in our culture, a sex role that is only now beginning to change.

Appendix

The first four measures of sensitivity to verbal cues were derived from the PONS test, a 47-minute film consisting of 220 2-sec audio and/or visual nonverbal stimuli. In each 2-sec segment, a 24-year-old female acts in one of 20 different emotional situations. The 20 situations are categorized with reference to four different types of emotion, each created by the crossing of two affective dimensions: positivity–negativity and dominance–submission. Hence, there are five positive-dominant situations (e.g., talking to a lost child), five negative-dominant situations (e.g., expressing strong dislike), five positive-submissive situations (e.g., expressing deep affection), and five negative-submissive situations (e.g., asking forgiveness). The situations were originally categorized as either positive or negative and as dominant or submissive according to the ratings of two different samples of judges (Rosenthal, Hall, Archer, DiMatteo, & Rogers, 1979; Rosenthal, Hall, DiMatteo, Rogers, & Archer, 1979).

The 220 PONS items consist of a random ordering of these 20 situations, each represented in 11 different "channels" of nonverbal communication. Three channels are pure video channels: face only, body only (neck to knees), and face plus body. Two channels are pure audio channels: "content filtered" (CF) and "randomized spliced" (RS). In both of these channels, verbal messages are rendered incomprehensible. CF preserves sequence and rhythm (RS does not); RS saves pitch and intensity. The other six channels are "mixed" channels, consisting of all audiovisual combinations of the two audio with the three video channels.

From each of the 220 items, subjects select one of two situational labels, one of which correctly describes the situation and one which incorrectly describes it. The incorrect alternative was assigned to each item by randomly choosing one of the 19 situation labels that was not the correct answer.

The fifth measure, the Nonverbal Discrepancy Test (NDT), employs 8 of the 20 situations of the PONS test, 2 from each of the four affective quadrants of the PONS. Half of the scenes in the NDT are represented in the face channel, and half are represented in the body channel. In addition, half of the scenes represented in each of these two video channels are also represented in the content-filtered audio channel, and half of the scenes are represented in the randomized-spliced audio channel.

In the discrepancy test, each of the 8 scenes is paired with every other scene twice. Hence, there are 128 items in the test (8 scenes × 8 scenes × 2 replications). Each item consists of the simultaneous pairing of either a face or a body with a content-filtered or randomized-spliced voice. Every possible audio–video pairing (face–CF, face–RS, body–CF, body–RS) occurs exactly 32 times. For one quarter of the items, the audio and the video segments are from the same affective quadrant (e.g., a positive-dominant face might be paired with a positive-dominant voice). One quarter of the items consist of audio and video segments from exactly opposite quadrants (e.g., a positive-dominant face might be paired with a negative-submissive voice). The audio and video segments of the remaining items differ on only one of the affective dimensions. For example, a positive-dominant face might be paired with a positive-submissive voice. In this case, the discrepancy would be along the dominance dimension, since both evaluative inputs are the same (i.e., both are positive). Or, a positive-dominant face might be paired with a negative-dominant voice. In this case, both inputs assume the same value on the dominance dimension (i.e., both are dominant) but they differ on the evaluative dimension (i.e., one is positive and the other is negative).

Subjects rate each scene on a 9-point scale of discrepancy. Their accuracy (or sensitivity) is a function of the degree to which they rate as more discrepant those scenes in which the video and audio channels are, in fact, more discrepant, compared to their ratings of the scenes in which the video and audio channels are, in fact, less discrepant.

Young Children's Preferred Attentional Strategies for Delaying Gratification

Brian T. Yates
American University

Walter Mischel
Stanford University

In four experiments, children controlled the frequency and duration of self-exposure to sets of stimuli during a delay of gratification. The stimuli included the real rewards for which they were waiting, symbolic (picture) versions of those rewards, or irrelevant objects. Previous research had shown that exposure to the real rewards hinders self-imposed delay, but viewing irrelevant stimuli or pictures of the rewards facilitates delay. In the present study, we recorded how long children viewed each stimulus during the delay and also assessed their verbal viewing preferences. Preschool children spontaneously tended to prefer to view the real rather than the symbolic stimuli, regardless of their relevance to the rewards in the delay contingency, both when the delay was self-imposed and when it was imposed externally. This generalized preference for attending to the "real rewards" rather than to more symbolic representations helps to explain why it is so difficult for young children to tolerate voluntary delay of gratification. By attending to the real rewards, they may make such delay especially frustrative and arousing, thereby defeating their own ability to wait for what they want. In contrast, children in Grades 1, 2, and 3 systematically selected effective attentional strategies during delay.

A great deal of experimental research has focused on the stimulus conditions that facilitate or impede delay of gratification. These studies have manipulated such variables as the presence or absence of the rewards and assessed how they influence the ability and willingness of subjects to tolerate various types of delay of gratification (e.g., Mischel, 1968, 1974; Mischel & Baker, 1975; Moore, Mischel, & Zeiss, 1976). The results provide much evidence about conditions that may facilitate waiting for deferred outcomes. In contrast, remarkably little is known about the subject's own natural attentional strategies for coping with various types of delay. Thus, we know a considerable amount about delay-enhancing stimulus conditions but almost nothing about children's preferred attentional strategies during delay of gratification. To begin to fill this gap, in the present set of studies we explored young children's verbal preferences and actual use of different attentional strategies for sustaining delay of gratification. Our results should help clarify the degree to which young children know and utilize delay-facilitating attentional strategies when faced with situations requiring them to wait for deferred but desired outcomes.

The delay of gratification paradigm used in the earlier research provided children with the dilemma of waiting for a more preferred but delayed reward or terminating their delay and getting a less preferred reward immediately (Mischel, Ebbesen, & Zeiss, 1972). Using this paradigm, several studies examined how attention to the delayed and immediate rewards changes children's ability to continu

to wait for the preferred outcome. Initially, it was predicted that attention to the rewards would facilitate delay of gratification. This prediction was based on Freud's (1911/1959) provocative idea that "cathecting" images of desired but blocked gratifications is a cornerstone for the development of frustration tolerance. Surprisingly, it was found that rather than facilitating delay by helping the subject anticipate the desired but blocked goal, attending to the delayed and immediate rewards appears to increase the child's arousal and frustration to the point where delay becomes too aversive to continue (Mischel, 1974). Specifically, the presence of the actual rewards during the delay period consistently produces shorter delay times than does the absence of the rewards (Mischel & Ebbesen, 1970; Mischel et al., 1972; Schack & Massari, 1973). When the rewards are not visible during delay, instructions to think about them have the same negative effect on delay time as do the rewards themselves (Mischel et al., 1972).

But while attention and thought directed at the real rewards hinder delay of gratification, attention to their symbolic representation, in the form of images (pictures of the rewards), facilitates delay (Mischel & Moore, 1973; Moore, 1974). Taken as a whole, these and related studies (e.g., Mischel & Baker, 1975; Moore et al., 1976) provide a coherent, theoretically meaningful set of rules that describe how attention to different types of stimuli can hinder or facilitate self-imposed delay of gratification. For the present investigation, the gist of these rules is that for preschool children, there are at least two basic strategies for using attention to facilitate delay of gratification and at least two basic attentional strategies that hinder delay. Attention to a symbolic or "cool" representation of the real reward objects that are in the delay contingency ("relevant rewards") as well as attention to comparable real objects that are irrelevant to the delay contingency ("irrelevant rewards") are effective strategies for self-imposed delay of gratification. Attention to the real, relevant rewards and attention to a symbolic representation of irrelevant rewards are both ineffective strategies that hinder delay, at least in the types of situations sampled in these studies.

In a recent series of related studies, Miller and Karniol (1976a, 1976b) have distinguished between self-imposed delay (SID) of the sort studied in the paradigm of Mischel and his associates and externally imposed delay (EID), in which the subject cannot voluntarily terminate the delay in favor of an alternative, immediate, but less preferred reward. Miller and Karniol believe that the findings of Mischel and associates apply to SID but not to EID. They argue that when individuals have no choice but to endure the delay, it is adaptive to focus on the rewards, and they have provided some empirical support for their view. Miller and Karniol's conclusions should still be seen as tentative, but their work does underline the need to distinguish between the two types of delay, and therefore, in the first study to be reported here, we included both the SID and EID paradigms.

Experiment 1

To investigate children's preferred attentional strategies for delaying gratification, the delay paradigm developed by Mischel et al. (1972) was modified. Instead of placing fixed stimuli in front of the child for the entire delay, we designed equipment that allowed the subject to self-regulate the presentation of stimuli throughout the delay period. Each child had available for self-presentation one of the two types of stimuli that facilitate SID and one of the two types of stimuli that hinder it. Different groups of children had available for viewing one of the four possible pairings of the two SID-facilitating and two SID-hindering stimuli. We recorded the amount of time that the children actually viewed the different types of stimuli during either a self-imposed delay of gratification (SID) or an externally imposed delay (EID) of equal duration and also assessed their preferences verbally after completion of the delay.

Table 1
SID-Facilitating and SID-Hindering Stimuli Available for Presentation in Different Stimulus-Pair Conditions

Stimulus pair		
SID-facilitating stimulus set	vs.	SID-hindering stimulus set
Picture of rewards (Relevant symbolic)		Actual rewards (Relevant real)
Irrelevant objects (Irrelevant real)		Irrelevant picture (Irrelevant symbolic)
Picture of rewards (Relevant symbolic)		Irrelevant picture (Irrelevant symbolic)
Irrelevant objects (Irrelevant real)		Actual rewards (Relevant real)

Note. SID = self-imposed delay.

Method

Overview and Design

Each child had one SID-facilitating and one SID-hindering set of stimuli available for viewing during the delay period. Two sets of stimuli exemplified the attentional strategies that have been found to hinder SID: (a) the actual rewards in the delay contingency (relevant real stimuli) and (b) a life-size color photograph of desirable objects that were irrelevant to the delay (irrelevant symbolic stimuli). Two other sets of stimuli exemplified the attentional strategies that have been found by previous research to facilitate SID: (c) a life-size color photograph of the rewards involved in the delay (relevant symbolic stimuli) and (d) a set of desirable objects that were irrelevant to the delay contingency (irrelevant real stimuli). All possible pairings of one set of delay-facilitating stimuli and one set of delay-hindering stimuli were tested. Table 1 lists the four stimulus-pair conditions used in this and the following studies.

In a 2 (SID versus EID type of delay) × 4 (stimulus pairs) factorial design, children were exposed to a delay of gratification while being able to self-present stimuli from one of the four types of stimulus pairs shown in Table 1. Duplicating the procedure used by Mischel and his colleagues for self-imposed delay of gratification (Mischel, 1974), we instructed children in the SID condition that they could terminate the delay at any time by pushing a button that rang a bell and signaled the experimenter to return. The children were also told that if they terminated the delay, they would receive the nonpreferred reward instead of the preferred reward. Children in the EID condition could not signal the experimenter to return. Instead, these children were yoked to children in the SID condition for duration of delay.[1] That is, if a child in the SID condition terminated the delay before the maximum time had elapsed, a child of the same sex in the EID condition was required to wait the same amount of time. The maximum delay period was 10 minutes.

Subjects and Experimenters

The subjects were 96 preschoolers (48 girls and 48 boys) who attended Bing Nursery School at Stanford University. Two male and two female experimenters tested equal numbers of male and female children in each cell of the design. Children were randomly assigned to conditions so that 6 males and 6 females participated in each cell of the design.[2] The children ranged in age from 3.0 to 5.2 years, with a mean of 4.4 years.

Apparatus

The experimental room resembled the one diagrammed in Mischel and Moore (1973). A visual barrier concealed a box of attractive toys in one corner. A small table and chair were set against the wall on the opposite side of the room. The chair was positioned inside a square that was outlined on the floor with black tape. Electromechanical equipment on the table enabled the child to control the frequency and duration of two stimulus sets. The buttons that the child pushed to present alternative stimuli for viewing required extremely little pressure to operate and were spaced 2 inches (5.1 cm) apart on the surface of a prominent metal box. The location of these buttons in relation to other apparatus is shown in Figure 1.

Two devices that contained the stimuli faced the child on his or her immediate right and left. Pushing the left button exposed the stimulus set on the child's left, and pushing the right button exposed the stimulus set on the child's right. An opaque cover was hinged to the back edge of the lower part of each device so that a solenoid held the cover open, presenting the set of stimuli for viewing only as long as the child continued to press the button. Stimuli were mounted at a 45° angle so that they were easily viewed by the child. When the child was not pressing the button, another solenoid held the cover closed, preventing the child from viewing stimuli without pushing a button. Only one device could be operated at a given time; pushing both buttons simultaneously exposed neither set of stimuli. To control for possible position preferences, half of the children in each cell

[1] Of course, the children were observed throughout the delay (through a one-way mirror), and the session would have been stopped immediately if the child appeared upset.

[2] Nine additional children began the experiment but were not included in the final sample because of problems with equipment or with the child's comprehension of instructions.

of the design had a stimulus set on their right, and the other children had the same stimulus set on their left.

Electromechanical equipment recorded the duration and frequency of the child's self-presentation of each stimulus set. Duration was recorded in units of .005 minutes. Relay circuitry initiated data recording automatically when the experimenter left the room and terminated data recording after 10 minutes.

Reward Stimuli

The alternative rewards used in the present study differed only in quantity; they were (a) three stick pretzels versus one stick pretzel (each pretzel was 7.6 cm × .3 cm) and (b) three regular-size poker chips (white, red, and blue) versus one regular-size poker chip (white). Half of the children in each cell chose between (and waited for) the food rewards, and the other children in each cell chose between (and waited for) the nonfood rewards. Thus, for the children who waited for food rewards, the stick pretzels were the relevant reward stimuli, and the poker chips were irrelevant. For the children who waited for poker chips, the poker chips were the relevant rewards, and the pretzels were the irrelevant stimuli, providing a complete crossover design. The stimulus pairs available for self-presentation included real and symbolic (picture) versions of the relevant and irrelevant items in the four combinations shown in Table 1. The four sets of stimuli from which these combinations were made were (a) three stick pretzels, (b) three poker chips, (c) a life-size color photograph of the three pretzels, and (d) a life-size color photograph of the three poker chips.

Procedure

Upon entering the room, the child was shown the toys that would be played with later. The experimenter then concealed the toys and asked the child to sit at a table on the other side of the room. The child was instructed to remain seated inside the square that was taped on the floor. The experimenter took a box from underneath the table, exposed the scheduled reward, and asked the child which alternative he or she would like to have. The experimenter explained that he or she would leave the room soon but would return later to give the chosen items to the child. These instructions were repeated until the child understood them. Afterwards, the rewards were returned to the box, which was then concealed under the table.

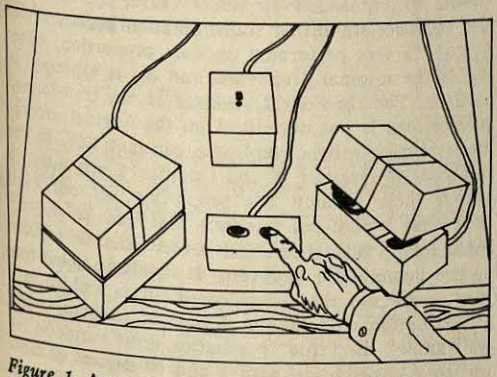

Figure 1. Apparatus for self-presentation of alternative stimulus sets, viewed from about 2 feet (61.5 cm) above child's eye level.

The experimenter proceeded to show the child how to use the stimulus presentation apparatus. So that the children would be less inclined to push both buttons simultaneously (a problem noted in pretesting), the children were asked to fold their hands together, to extend their forefingers, and to keep their forefingers together throughout the session. In essence, this procedure prevented the children from pushing both buttons simultaneously. After folding his or her hands and fingers together, the child was encouraged to push the buttons. Whenever the child pushed a button, the experimenter named the presented stimulus set, noting whether it was a set of real objects or a picture of real objects (e.g., "Oh, look! That button shows you a real _____ and a real _____!" or "Oh, look! That button shows you a picture of _____ and a picture of _____!"). The child was instructed to look closely at whichever stimuli were exposed, and the experimenter modeled intent viewing of whichever stimuli the child self-presented.

After the child had become familiar with the stimuli and the apparatus by presenting each stimulus set at least three times, he or she was asked not to push both buttons at the same time and not to touch the devices or stimuli. The child was then quizzed on which button produced which set of stimuli, to be certain that the child knew which stimuli were available for viewing and how to present each of the available stimulus sets. In this study, the children were given no specific instructions about how to structure their viewing of the alternative stimuli during the delay; they were simply asked to "push the buttons." The children also were not given specific information about when the experimenter would return but simply were reassured that the delay would not be "too long."

The experimenter left the room after reminding the child that he or she would play with the toys later. During the delay, the experimenter observed the child through a one-way mirror and returned to the room after 10 minutes. The child was then again shown the reward items and was asked which he or she was supposed to receive. All children remembered which one they previously had chosen to receive, were given that object, and next were asked the following questions in random order:

Question 1. If you could have just one of these (stimulus sets) in front of you while you were

Table 2
Stimulus Preferences in Each Pair on Each Measure (Experiment 1)

Stimulus pair	Measure: Question 1 (choice)	Measure: Question 2 (liking)	Measure: Viewing time
Relevant Real vs. **symbolic**	.83***	.75**	.57**
Irrelevant **Real** vs. symbolic	.83***	.71*	.59***
Symbolic **Relevant** vs. irrelevant	.79**	.62	.53
Real Relevant vs. **irrelevant**	.58	.62	.49

Note. The data are proportions: The larger the proportion, the greater the preference for the top stimulus in each pair. $n = 24$ for all measures. Stimuli that facilitate self-imposed delay (SID) are in boldface type. In all tables, proportions for Question 1 and Question 2 are not directly comparable to proportions for viewing time (see text). For Questions 1 and 2, binomial tests compared the data to chance levels; for viewing time, t tests compared the means to an ideal neutral proportion of .50. All tests are two-tailed throughout this article.

* $p = .06$.
** $p < .025$.
*** $p < .002$.

waiting, which one would you want in front of you all the time while you were waiting?
Question 2. Which one (of the stimulus sets) did you like to see the most while you were waiting?

After recording the child's answer, the experimenter led the child to the toys and, after they had played with them for 5 to 10 minutes, returned the child to the nursery school classroom.

Results

Children's answers to the postdelay questions and the relative amount of time they spent viewing alternative stimuli showed a consistent pattern: They preferred to view real stimuli regardless of their relevance to the delay (see Table 2) and regardless of the type of delay (EID or SID).

Answers to the postdelay questions were analyzed in terms of the proportion of children in a given cell of the design who answered the question by pointing to the delay-facilitating stimulus in the stimulus pair.[3] The relative amount of time spent viewing the delay-facilitating stimulus in a given pair was calculated for each child separately as the duration of viewing the delay-facilitating stimulus divided by the total duration of viewing both stimuli.

Preliminary analyses found no significant effects of food versus nonfood rewards. Separate analyses of variance conducted on the three measures found no significant main effects or interactions of SID versus EID: both Fs < 1 for the two questions; $F(1, 88) = 2.47$, $p > .10$, for relative time spent viewing stimuli.

To examine the effects of stimulus pairs, we combined data for types of delay within each stimulus-pair condition. These analyses showed a consistent pattern on all three measures. More specifically, the proportions in Table 2 express the relative preference for the stimulus listed first in each pair. When given a choice between relevant real versus relevant symbolic stimuli, the children preferred the real stimuli: $p < .002$ by a two-tailed binomial test for Question 1; $p = .02$ by a two-tailed binomial test for Question 2; $t(88) = 2.71$, $p < .01$, two-tailed, for time

[3] As recommended by Winer (1971, pp. 399–401), the variance-stabilizing transformation $\phi_{jk} = 2 \arcsin [(p_{jk})^{1/2}]$ was performed on each proportion, where p_{jk} is the original proportion and ϕ_{jk} is expressed in radians. The theoretical variance of the transformed proportions is not dependent on the original proportions and instead is simply the constant $1/N$. In the analyses of Question 1 and Question 2 responses, in which there is only one proportion per cell (and hence no within-cell variance that can be directly calculated), this theoretical error variance is used as the denominator in F tests. It should be noted that just as we use the normal distribution (which is a t distribution with infinite degrees of freedom) when we "know" the "true" population error variance, we use an F distribution with k and ∞ degrees of freedom when we know the true or "theoretical" error variance (cf. Langer & Abelson, 1972, for an example and extended discussion of this procedure).

spent viewing stimuli.[4] When given a choice between irrelevant real and irrelevant symbolic stimuli, children again preferred the real stimuli: $p < .002$ by a binomial test for Question 1; $p = .06$ by a binomial test for Question 2; $t(88) = 3.48$, $p < .002$, for time spent viewing stimuli. In contrast, children who could not choose between real and symbolic stimuli, but only between relevant and irrelevant stimulus sets that were both real or both symbolic, did not exhibit a consistently significant preference for either relevant or irrelevant stimuli: $p < .01$ in favor of relevant symbolic as opposed to irrelevant symbolic stimuli for Question 1; but $p > .30$ for Question 2 in the same stimulus pair; and $p > .30$ for both Question 1 and Question 2 in the relevant–real versus irrelevant–real stimulus pair. In addition, children did not exhibit a significant preference when actually viewing relevant versus irrelevant stimuli during the delay, regardless of whether both stimuli were symbolic or real ($ts < 1.2$; $ps > .20$).

Fourfold point correlations (Hays, 1963) showed that the three measures were significantly and substantially correlated with one another: $\phi = .43$, $p < .001$, between Question 1 and viewing; $\phi = .34$, $p < .005$, between Question 2 and viewing; $\phi = .55$, $p < .001$, between Question 1 and Question 2.

Before discussing the significance and implications of the results of the first study, we will describe two additional experiments; then the meaning of the total pattern of data will be examined.

Experiment 2

Because important changes in ideation and imagery may occur during the preschool years (e.g., Paivio, 1971; Piaget & Inhelder, 1966), our second study was developmental and systematically included children from three age groups: 3.00 to 4.25 years, 4.50 to 5.75 years, and 6.00 to 7.00 years. Thus, we used a 4 (stimulus pairs) × 3 (age groups) factorial design. Given the finding in Experiment 1 that preference patterns were highly similar for SID and EID, in our second experiment (and also in the third one to be reported in this article) we used only the EID paradigm, because it controlled length of delay time, thus preventing stimulus-viewing proportions from being confounded with duration of delay. Except for this change and for differences in the specific relevant and irrelevant reward stimuli used, the basic procedures and measures were essentially identical with those in Experiment 1.

Method

Reward Stimuli

To extend the generalizability of findings, somewhat different sets of reward stimuli were used. Specifically, the stimulus sets used in Experiment 2 were (a) one stick pretzel and one miniature marshmallow, (b) one small red poker chip (.75 inches, or 1.9 cm, in diameter) and one penny, (c) a life-size color photograph of the pretzel and the marshmallow, and (d) a life-size color photograph of the poker chip and the penny.

Half of the children in each cell of the design chose between receiving one pretzel and one marshmallow, and the other children in each cell chose between receiving one poker chip and one penny. Thus, for the former groups of children, the pretzel and marshmallow were the relevant reward items, and the poker chip and penny were the irrelevant items. For the other group of children, the poker chip and penny were the relevant reward items, and the pretzel and marshmallow were the irrelevant items. To avoid differences in stimulus viewing that might result from different durations of delay or from different durations of exposure to alternative stimuli, all children were exposed to a fixed period (12 minutes) of EID. Children were tested in random order in terms of stimulus-pair condition, age group, gender, and experimenter.

Subjects and Experimenters

The subjects were 96 preschool children (48 girls and 48 boys) who attended Bing Nursery School at Stanford University. Each cell of the design included 4 male and 4 female children. Two children of each sex delayed food gratification (pretzel/marshmallow), and two children of each sex delayed nonfood gratification (poker chip/penny). Two female and two male experimenters tested equal proportions of the children in each cell of the design.

---

[4] These t tests used the error term from the preceding analysis of variance as the pooled estimate of standard deviation, $(MS_e/n)^{1/2}$. These and all t tests in this article are two-tailed.

** $p < .025$.
*** $p < .002$.

Results

Children's answers to the postdelay questions and the relative amount of time that they actually spent viewing the alternative stimuli again showed the same consistent pattern. As summarized in Table 3, both verbally and behaviorally, children preferred to view real stimuli regardless of their relevance or irrelevance to the delay contingency.[5]

Separate analyses of variance conducted on the three measures revealed no significant main effect or interactions of age group (all Fs < 1). To examine the effects of stimulus pairs, subsequent analyses combined data for age groups within each stimulus-pair condition.

These analyses showed a consistent pattern on all three measures that closely matched the results of Experiment 1. Specifically, when given a choice between relevant real versus relevant symbolic stimuli, the children preferred real stimuli. Two-tailed binomial tests yielded $p < .002$ for Question 1 and $p = .06$ for Question 2; $t = 2.90$, $p < .01$, for time spent viewing stimuli. Similarly, when given a choice between irrelevant real and irrelevant symbolic stimuli, children preferred the real stimuli: $p < .002$ for Question 1; $p = .06$ for Question 2; $t(84) = 3.31$, $p < .002$, for time spent viewing stimuli. When the children could not choose between real and symbolic stimuli, but only between relevant and irrelevant stimulus sets that were both real or both symbolic, no significant preferences were found on any measure. Children who had these stimulus sets available showed a nonsignificant tendency to prefer relevant stimuli (ps $= .15$ for Question 1; ps $\geq .15$ for Question 2; ts ≤ 1.3 for time spent viewing stimuli).

Fourfold point correlations measured the strength of intermeasure relationships. The three measures were again significantly correlated with each other: $\phi = .35$, $p < .001$, between Question 1 and stimulus viewing; $\phi = .39$, $p < .001$, between Question 2 and stimulus viewing; $\phi = .42$, $p < .001$, between Question 1 and Question 2. The strength of intermeasure relationships did not change systematically as a function of age group. Between Question 1 and stimulus viewing, the correlations were .27, .23, and .32 for the 3.00 to 4.25-year-old, the 4.50 to 5.75-year-old and the 6.00 to 7.00-year-old groups, respectively (all ps $>$ .05). Between Question 2 and stimulus viewing, correlations were .62 ($p < .001$), .15, and .44 ($p < .025$) for the three age groups respectively. The correlations between the two questions were .22 (ns), .56 ($p < .005$), and .47 ($p < .01$) for the three age groups respectively.

Experiment 3

The results of Experiment 2 strengthen the generality of the findings from Experiment 1 and are completely consistent with it. Regardless of age, preschool children tend to prefer

[5] As in Experiment 1, analyses of variance revealed no significant effects due to the food–nonfood variation in Experiment 2 or in Experiment 3.

view whichever stimuli are real, during delay of gratification. Before reaching any firm interpretations and conclusions, however, we conducted a third experiment designed to overcome some possible ambiguities. Namely, in the first two experiments, the viewing instructions to the children simply requested that they push buttons exposing stimuli during the delay period. Likewise, the postdelay questions may have been somewhat ambiguous. Can we be sure that the children's responses reflected attentional strategies that they believed would help them wait? Instead, might they have viewed whatever they found more attractive or desirable (i.e., real objects rather than pictures of them)? Might the children's viewing and verbal preferences for the real stimuli possibly have been the result of trying to "tell" the experimenter that they wanted to receive one of the sets of real objects after the delay, instead of receiving a picture of those objects? Conceivably, the children could have thought that the experimenter would somehow know which stimuli they viewed most during the delay. In that case, they might have conjectured that what they viewed during the delay would influence what the experimenter gave them when he or she returned. Likewise, the children may have self-presented real rather than symbolic stimuli so that when the returning experimenter opened the door to the room, he or she would see the children looking at the real stimuli and might be more likely to give them the real objects rather than pictures of them.

To identify the meaning of the children's responses more precisely, in Experiment 3 we explicitly asked half the subjects to view those stimuli that would best facilitate delay (efficacy strategy) and half to view those stimuli that they wanted to see (wish strategy). Moreover, we carefully arranged the situation and the postdelay questions to avoid alternative interpretations.

Method

In an EID situation, half of the children in each of the four stimulus-pair conditions were instructed to view those stimuli which, in their opinion, would best help them wait (efficacy strategy). The remaining children in each stimulus-pair condition were asked to view those stimuli which they wanted to see (wish strategy). Thus, we used a 2 (viewing instructions) × 4 (stimulus pairs) factorial design.

The same rewards and stimuli used in Experiment 1 were used in Experiment 3. As in the first two studies, rewards and relevancy of stimuli were completely crossed within the design. Because Experiment 1 found no significant difference on any measure between SID and EID, in Experiment 3 we again used only EID to provide maximum control over duration of delay.

Subjects

A total of 80 children (40 girls and 40 boys) who attended Bing Nursery School were the subjects. Four female experimenters tested equal proportions of the 5 girls and 5 boys who were randomly assigned to each cell in the design. The children ranged in age from 2.7 to 5.4 years, with a mean age of 4.3 years.

Procedure

The procedure used in the first two studies was modified as follows: The children were assured that the experimenter would not know anything about what they did during the delay. The children also were told that the experimenter would knock on the door three times before reentering the room and at that time they should stop looking at either stimulus set and, instead, should place their hands on top of their heads as soon as the experimenter knocked on the door. Furthermore, a tall (approximately 8 feet, or 2.44 m, high) divider was placed between the door and the table at which the children sat. The children were told that in case they forgot to put their hands on their heads when they heard the experimenter knock, the divider would prevent the experimenter from seeing which stimuli they might be looking at.

Just before leaving the room, the experimenter consulted a previously concealed portion of the schedule sheet to find out which predelay stimulus-viewing instructions the child was to receive. Half the children were given the *efficacy strategy* and were told the following:

> Push the button that shows you what *helps you wait* the most. . . . Look at the one (stimulus set) which makes it easiest for you to wait.

The other half were given the *wish strategy* and were told to:

> Push the button that shows you what you *like to see* the most while you're waiting. . . . Look at the one which you like to see the most.

Upon returning to the room after the delay, the experimenter gave the child the promised reward. She

*** $p < .002$.

then asked two questions. The first question of the previous experiment was revised to make it more direct:

> Please tell me which one (of the two stimulus sets) showed you what *helped you wait* the most. Which one made it easiest for you to wait?

The second question remained quite similar to Question 2 in Experiments 1 and 2:

> Please tell me which one showed you what you *liked to see* the most. Which one did you want to look at?

Both questions were asked of all children in a forced-choice format and in random order.

Results

Separate analyses of variance for the three measures yielded no significant main effects of predelay viewing instructions (all Fs < 1). The Instruction × Stimulus Pair interaction did not reach significance for time spent viewing stimuli, $F(3, 72) = 2.12$, $p > .10$, or for Question 2, $F(3, \infty) = 1.23$, $p > .20$. However, there was a significant interaction of Instructions × Stimulus Pairs on Question 1, $F(3, \infty) = 6.15$, $p < .001$.[6] As Table 4 indicates, this interaction reflects the fact that children who had been given a wish strategy overwhelmingly chose the relevant real (rather than relevant symbolic) stimuli while showing no strong preference for relevant real versus irrelevant real stimuli. In contrast, subjects given the efficacy strategy showed no systematic preference for relevant real versus relevant symbolic stimuli, but did choose relevant real over irrelevant real stimuli.

The overall data are summarized in Table 4. Let us consider each measure separately.

During the delay, children tended to actually view the relevant real more than the relevant symbolic stimuli when given a predelay wish strategy (i.e., when asked to self-present the stimuli they would like to see the most while waiting); $t(72) = 2.75$, $< .01$. But as Table 4 shows, children who

[6] Recall (Footnote 3) that since the theoretical error variance of transformed proportions was used in analyses of Questions 1 and 2, an F distribution with k and ∞ degrees of freedom was used for all significance tests.

had been asked to self-present the stimuli that would help them wait the most (efficacy strategy) showed no such systematic preferences; they viewed the relevant symbolic stimuli as much as they did the relevant real rewards.

On Question 2, the postdelay measure asking which stimuli they had liked to see most, children significantly preferred real stimuli to symbolic ones ($p < .05$ for both stimulus pairs). In addition, children who were given the efficacy viewing strategy showed a significant preference for irrelevant real over irrelevant symbolic stimuli when asked which they "liked" to view ($p < .025$), but not when asked which *helped* them wait best ($p > .10$). Finally, consider Question 1, the postdelay question asking children which stimuli had helped them wait the most. Here the answers again depended on the predelay viewing instructions (as the previously noted significant interaction indicated). Specifically, when children had been given the wish strategy instructing them to view the stimuli they liked to see the most, they consistently preferred relevant real over relevant symbolic stimuli ($p < .002$), paralleling the results found in Experiments 1 and 2. But when they had been instructed to view the stimuli that would help them wait most (efficacy strategy), they did not report any significant preference for relevant real over relevant symbolic stimuli, choosing each equally often.

Note also that on Question 1, children who had been given the predelay efficacy strategy preferred relevant real to irrelevant real stimuli. Since these children were waiting in an EID situation, their belief that attention to relevant real rewards would help them wait more than attention to irrelevant real stimuli may appear to support Miller and Karniol's (1976a, 1976b) view that while attention to the actual rewards impedes self-imposed delay, it facilitates externally imposed delay. Before reaching that conclusion, however, we must take into account some other considerations. First, Miller and Karniol's subjects were several years older than ours. Second, contradictory evidence comes from a fourth study that we conducted with subjects of comparable age to those used by Miller and Karniol, as reported next.

Experiment 4

In this final study, we examined the stimulus preferences of older (elementary school) children. We concentrated on their preference for relevant versus irrelevant real stimuli, since that is the most theoretically interesting choice, but continued to distinguish between EID and SID situations and between food and nonfood delay. We assumed that these older, more developmentally mature subjects would have a better awareness of the attentional strategies that would facilitate delay and that this awareness would be reflected in their stimulus preferences.

Method

In an EID or SID situation, half of the children waited for food rewards and half waited for nonfood rewards. Thus, we used a 2 (EID vs. SID) × 2 (food vs. nonfood rewards) design with 12 children in each cell. Rewards and relevancy of stimuli again were crossed completely in the design. The child's choice in each condition was between viewing the relevant real stimuli (the actual rewards in the delay contingency) or the irrelevant real stimuli (real stimuli irrelevant to the delay contingency).

Subjects

The data came from 48 children (24 girls and 24 boys) who attended Grades 1, 2, or 3 in one of two local elementary schools (Kirk and Valley View Elementary Schools in San Jose, California). One male experimenter conducted the predelay procedures; an experimentally blind assistant administered the postdelay questions about the delay-facilitating characteristics of stimuli. A male and two female adults served as assistants, for the same proportion of children in each cell.

Procedure

The same procedure was employed in Experiment 4 as in the other studies, with the following modifications made because of the age of this subject population. The rewards used in earlier studies were changed to be more appropriate for older children. Specifically, these children waited for either two versus six regular-size cat's-eye marbles or for one half a cookie versus three cookies (half a sugar cookie vs. a chocolate chip, an oatmeal, and a sugar cookie, each 3 inches, or 7.6 cm, in diam-

Table 5
Stimulus Preferences on Each Measure in Each Condition (Experiment 4)

Condition	Food		Nonfood	
	Question 1 (choice)	Viewing time	Question 1 (choice)	Viewing time

EID	.25**	.43	.79**	.69***
Total	.23***	.42*	.75***	.71***

Note. SID = self-imposed delay; EID = externally imposed delay. The larger the proportions, the greater the preference for relevant real versus irrelevant real stimuli. $n = 24$ for Question 1; $n = 12$ for viewing time.
* $p < .05$.
** $p < .025$.
*** $p < .002$.

eter). To collect more data on stimulus preferences during the delay, the apparatus was altered slightly so that children could alternate stimulus sets, determining how long each set was presented. The child chose which stimulus set was viewed, but always viewed one of the two stimulus sets. As in the previous studies, the children were assured that the experimenter would not know what they were doing during the delay, but no tall divider was used, and no hands-on-head instructions were given. As in Experiments 1 and 2, the children were not given specific viewing instructions. The delay period was increased to 20 minutes, in view of the children's age and to collect more extended data on stimulus viewing.

Verbal stimulus preferences (Question 1) were obtained after the delay by having the assistant ask the child which stimulus would be best to view for food delay and, separately, for nonfood delay, regardless of whether the child had experienced a food or nonfood delay. For subjects in the SID condition, this question was phrased as follows:

> Suppose that you would get these (food or nonfood rewards) if you waited for (experimenter's name) to come back on his own. Also, suppose that you would get (this) (these) if you pushed this (the termination) button and called (the experimenter) back. While you're waiting, would looking at what's under this (assistant points to left) box lid help you wait? Or, while you're waiting, would it help you wait more if you looked at what's under this (experimenter points to right) box lid? Looking at which would help you wait better?

In the EID condition, the question was rephrased to describe an EID rather than SID situation. Half of the children in each experimental cell were asked the question first for food delay, and half were asked the question first for nonfood delay.

Results

An analysis of variance for proportions of time spent viewing the alternative stimuli found no significant main effect for SID versus EID situations ($F < 1$) and no Delay Situation × Rewards interaction ($F < 1$). There was, however, a significant main effect for food versus nonfood rewards, $F(1, 44) = 28.85$, $p < .001$.

Verbal stimulus preferences also were not significantly affected by SID versus EID situations ($F < 1$ for all children's answers to the food delay question; $F < 1$ for answers to nonfood delay questions). The data for Question 1 in Table 5 show that these children said that they preferred viewing irrelevant real stimuli significantly more than relevant real stimuli during externally imposed, as well as during self-imposed, delays of food gratification (ps $< .025$, binomial tests). When SID and EID preferences are pooled, the preference for viewing irrelevant rather than relevant real stimuli is even more significant ($p < .001$). Consistent with these verbal preferences, the children spent significantly more time actually viewing the irrelevant stimuli during delay of food rewards, $t(44) = 2.11$, $p < .05$, two-tailed, for SID and EID pooled.

In contrast, these subjects significantly preferred relevant real over irrelevant real stimuli during delays of *non*food gratification, whether EID ($p < .025$ for verbal pref-

erence); $t(44) = 3.55$, $p < .002$, for viewing preference, or SID ($p < .05$) and $t(44) = 4.30$, $p < .002$. Possible reasons for this effect are explored in the discussion.

Further analyses examined the role of age in the children's viewing preferences. We divided the children into three age groupings: (a) less than or equal to 7 years ($n = 9$), (b) greater than 7 years but less than or equal to 8 years ($n = 17$), and (c) greater than 8 years ($n = 22$). Chi-square tests of the number of children in each age group who preferred to view irrelevant or relevant real rewards revealed that verbal stimulus preferences were not affected systematically by age, $\chi^2(2) = 1.99$, $p > .30$, for food delay; $\chi^2(2) < 1$ for nonfood delay. Moreover, the proportion of the delay spent viewing relevant real stimuli was not significantly different across age groupings. Specifically, in a three-way analysis of variance for viewing proportions, the only significant effect or interaction was the main effect for food versus nonfood delay, $F(1, 36) = 25.96$, $p < .001$; all other Fs < 1.5. Correlations between age and viewing preferences (verbal and nonverbal) were all nonsignificant and low for food and nonfood delay, both for EID and SID separately and pooled.

General Discussion and Conclusions

Taken as a whole, the results of the present series of experiments lead to several conclusions concerning the nature and consequences of young children's preferred attentional strategies during delay of gratification. To recapitulate briefly, Experiment 1 showed that during both self-imposed delay (SID) and externally imposed delay (EID), preschool children prefer to view real stimuli rather than symbolic (pictorial) representations of them, regardless of their relevance to the rewards in the delay contingency. No differences in preference patterns were found in SID versus EID. The same pattern of preferences was replicated in Experiment 2, which also found no significant effects of age within the three age categories sampled (ages 3 to 4.25 years, 4.50 to 5.75 years, and 6.00 to 7.00 years).

Experiment 3 allowed us to distinguish clearly between children's attentional preferences during delay when they are oriented to attend to the stimuli that they want to view (wish strategy) as opposed to those stimuli that they believe would most help them wait (efficacy strategy). The results revealed that when following a wish strategy, children attended significantly more to the real rewards than to their more abstract (pictorial) representations, further replicating the findings of Experiments 1 and 2. But when following an efficacy strategy, the children did not show any systematic preference for viewing relevant real as opposed to relevant symbolic stimuli: Presumably, they simply did not know which of these two types of stimuli would help more and chose quite randomly.

The young subjects of the first three experiments attended as much to relevant real as to irrelevant real stimuli during delays and preferred the two equally, again indicating a lack of awareness of delay-facilitating attentional strategies. This lack of discrimination was found consistently in all three experiments, and on all measures, with only one exception: Namely, on Question 1 in Experiment 3, children who had been given the predelay efficacy strategy significantly preferred relevant real to irrelevant real stimuli.

The data from the older children (Grades 1, 2, 3) obtained in Experiment 4 were dramatically different and suggest a change in delay strategies in the course of development, beginning around the age of 7 years. Specifically, when waiting for food, these older children systematically preferred viewing nonfood stimuli and were aware that this strategy would help them delay gratification best. This was true in externally imposed as well as in self-imposed delay situations. Thus, the older children, in sharp contrast to the younger ones in Experiments 1, 2, and 3, preferred to view the irrelevant stimuli during food delay. This finding supports the view that in the course of development, the child becomes aware of effective delay strategies and realizes that attention to the rele-

vant reward stimuli impedes effective delay in EID as well as in SID situations.

The fact that the older children also preferred to view the irrelevant stimuli during externally imposed food delay raises important theoretical questions about the attentional strategies that actually facilitate or impede such EID. A great deal of direct evidence supports the conclusion that self-imposed delay (SID) is impeded by attention to the relevant real rewards (e.g., Mischel, 1974; Mischel et al., 1972; Moore et al., 1976; Schack & Massari, 1973). In contrast, the conclusion of Miller and Karniol (1976a, 1976b) that externally imposed delay is helped by attention to the rewards was based entirely on indirect evidence, such as indications of differential frustration during reward absence versus reward presence in the course of EID, inferred from such data as subjective time estimates. The present data therefore raise the possibility that firm conclusions about the facilitating effects of attention to the rewards during EID may be premature. If an attentional strategy that focuses on the rewards really facilitates EID, it seems unlikely that the relatively mature subjects sampled in Experiment 4 would systematically tend to reject it during food delay, while younger subjects were more likely to prefer it (in Experiments 1, 2, and 3). Unfortunately, a direct test of the efficacy of different attentional strategies on actual duration of EID is not possible. By definition, EID requires that the subject cannot control the length of actual waiting time, thus preventing such a direct test of the effects of any stimulus manipulations upon duration of externally imposed delay.

So far we have discussed the preferred attentional strategy of the older children only during food delay. But recall that when waiting for nonfood rewards, the older children preferred to view the actual rewards in the delay contingency (i.e., the relevant real stimuli), during both EID and SID. This preference might seem puzzling and contradictory. However, it becomes understandable when one examines more closely the children's specific choice in this nonfood delay condition. Namely, in this condition of the cross-over design, food became the irrelevant stimulus. Thus, while waiting for a nonfood object, the subject's choice was either to view that nonfood stimulus or a food treat not relevant to the delay contingency. It seems likely that the older children realized that if they chose to view the food during the delay, they would be frustrating themselves (by arousing their desire for a consumable but unavailable object) more than they would if they viewed the relevant nonfood object. That is, while waiting for marbles, it may well be less frustrating to view those objects than to view cookies. In future research, tests of preference for relevant versus irrelevant stimuli probably should include both relevant and irrelevant food stimuli or both relevant and irrelevant nonfood stimuli, in order to avoid conflicts between the two different types of categories.

Taken as a whole, the present series of studies suggests a clear shift in preferred attentional strategies at the age of approximately 7 years. Specifically, the first three experiments unequivocally show that preschool children do not systematically prefer or use attentional strategies that have been found to optimize self-imposed delay of gratification (SID).[7] Indeed, the observed tendency of preschool children in Experiments 1, 2, and 3 to prefer attending to real stimuli (rather than to pictorial or abstract representations) may make it especially frustrative and difficult for them to engage in sustained voluntary waiting for preferred but delayed gratifications.

Our finding that the younger children (Experiments 1, 2, and 3) spontaneously prefer to view the real stimuli during delay of gratification seems to be congruent with

---

[7] Follow-up studies using simpler choices to explore knowledge of delay suggest that awareness of at least one basic delay rule—that it helps to cover rather than expose the rewards while waiting for them—may begin to emerge even earlier. In one study, most children knew that it would help to cover rather than expose the rewards by the time they were 5 years old (Mischel, Mischel, & Hood, Note 1). Even simpler or more ingenious methods might of course reveal important knowledge about self-control at still younger ages.

Freud's (1911/1959) classical theory of wish-fulfilling ideation during delay: When the desired object is blocked, the frustrated child tries to self-present it, to "have it." But our previous research suggests that in so doing, young children are making self-imposed delay even more difficult for themselves by increasing their desire and hence enhancing the frustrativeness of the delay (e.g., Mischel, 1974)—especially if this ideation is consummatory rather than more abstract (Mischel & Baker, 1975; Moore et al., 1976). The youngsters are then trapped in a delay-defeating cycle, attending to the consummatory qualities of what they really want and becoming increasingly frustratively aroused, thereby making it even harder to wait successfully. These interpretations are supported by the fact that, at least in the SID paradigm, it has been demonstrated repeatedly that attention to the real stimuli increases the frustrativeness of the delay and reduces the length of voluntary waiting (Mischel, 1974; Schack & Massari, 1973; Toner & Smith, 1977; also see Yates, 1977).

The young children's preferences for real stimuli over abstract or symbolic ones in the delay situation, and their inability to discriminate effective and ineffective delay strategies, probably reflect their cognitive-developmental immaturity. With greater cognitive development, the child comes to recognize and prefer attentional strategies that avoid frustrative arousal (Experiment 4). As children increase their ability to deal with stimuli more abstractly, they can transform them in delay-facilitating ways (Mischel, 1974; Moore et al., 1976). Specifically, we suggest that the older child can focus more on the abstract rather than consummatory qualities of incentives, thereby avoiding excessive frustration while remaining oriented to, and guided by, preferred but delayed goals.

Strategy Signals in Face-to-Face Interaction

Starkey Duncan, Jr., Lawrence J. Brunner, and Donald W. Fiske
University of Chicago

The notion of "strategy signal" is proposed as an element in the description of face-to-face interaction. Strategy signals are actions by a participant that have a distinct and consistent effect on specified subsequent actions by the partner, but that have been rejected as signals within the organization of interaction. Data are presented on three hypothesized strategy signals in eight two-person conversations. Both the speaker's head direction toward the auditor and the number of turn cues have the effect of increasing the auditor's attempts to take the turn under certain circumstances. Speaker smiling has the effect of increasing auditor smiles. The role of strategy signals within the broader description of face-to-face interaction is discussed.

We are proposing a new component of face-to-face interaction, the strategy signal: one or more actions by a participant that have a distinct and consistent effect on a specified subsequent action by the partner. Because the full definition of a strategy signal requires the prior notions of organization (or structure) and of strategy in interaction, as well as a certain approach to research method, we turn first to these matters.

Describing the organization of interaction is not unlike describing language in terms of grammar. A hypothesized organization for interaction would contain elements such as signals (composed variously of actions in language, paralanguage, body motion, and the like) and rules for appropriately using and responding to these signals. The organization as a whole provides a structure for the proper conduct of the interaction. A program of research in this laboratory (Brunner, in press; Duncan, 1972, 1974; Duncan & Fiske, 1977; Duncan & Niederehe, 1974) has attempted to describe some aspects of the organization of certain two-person conversations between adults. Because the research is concerned with the organization of interaction (as opposed to individual messages), analyses are based on sequences of action involving both participants.

A complete description of face-to-face interaction, however, would include consideration of interaction strategy in addition to organization (Duncan & Fiske, 1977). The notion of interaction strategy is a basically simple one. A close analogy is found in games such as chess or baseball. If the organization of face-to-face interaction is analogous to the rules of a game, then interaction strategy is analogous to ways of playing the game. For example, one rule in tennis is that the player must return the ball into the opponent's court, this rule leaving to the player's strategy the decision where to place the ball within that court. And within the rules for baseball, a batter may choose to swing or not at a given pitch. In this sense, our use of the term, though confined to describing face-to-face interaction, is congruent with one of its major meanings in common usage. Of course, the notion of strategy is common in social science.

In general, interaction strategy arises whenever there are options attaching to the rule-based organization of interaction. We may think of two broad types of option. One type has to do with legitimate alternatives within the rules. In the organization hypothesized for aspects of some two-person conversations (Duncan & Fiske, 1977), an example of a legitimate option would be the auditor's choice to take the turn or not upon activation of the turn signal by the speaker. Each such choice would constitute an element of the auditor's strategy in the interaction.

Not all rules for interaction involve legitimate alternatives. For example, it would seem that if someone offers to shake hands with another, the recipient of that offer does not have a legitimate option to refuse, except under highly specialized circumstances (such as demonstrably dirty hands), for which apologies are given. In such cases where the rules require the taking or avoiding of certain actions, there remains the option simply to violate the rules. The refusal to shake hands without extenuating circumstances is presumably a rule violation; similarly, an interruption is a violation of the turn-signal rules. Thus, rule violation—or its absence—is another aspect of interaction strategy.

One component of strategy—rule violation—is always present in interaction, whereas the other—legitimate alternatives—is present only when it is provided for by the rules. Of course, rules providing for legitimate alternatives may be prevalent in many interactions. In any event, because of the presence of optionality, engaging in rule-based interaction requires a participant to choose a course of action continuously with respect to rule violation, and also at each point at which there are legitimate alternatives.

Organization, Strategy, and Action Sequences

To this point, distinctions have been made (a) between organization and strategy in interaction and (b) between rules that provide for legitimate alternatives and those that do not. These distinctions may be directly related to research on action sequences. Consider a sequence A–B, in which A is a action by one participant, and B is a sub sequent action by the partner. Let us assum that a sufficient number of A's and B's hav been observed in one or more face-to-fac interactions and that an A is sometimes, bu not always, followed by a B. In this case, i a relationship between A and B exists withi the organization of interaction, then B an not-B would have to be considered legitimat alternatives upon the occurrence of A. A example would be the hypothesized turn sig nal, which was sometimes, but not always followed by an auditor's attempt to take th turn.

Given these data, there are two types o questions we may ask of the relationship be tween A and B. First, given an occurrenc of A, what is the probability that it is fol lowed by B? We shall call this the prob ability of a consequent—certainly the most common perspective in studies of action sequences. But of course we may also ask the reverse: Given an occurrence of B, what is the probability that it is preceded by A? We shall call this the probability of an antecedent.

The distinction between the probability of a consequent and the probability of an antecedent provides us with an analytic framework for implementing the distinction between organization and strategy. When rules providing for legitimate alternatives are at issue (as they are in this example), evidence relating to the organization of interaction is presented in terms of probabilities of antecedents. That is, to support a hypothesized rule for the action sequence A–B in which B and not-B are considered legitimate alternatives, the data would optimally show that each B was preceded by an A; the probability of that antecedent is 1.00. As with the turn signal, the hypothesized rule would state that B may appropriately occur only after A, but need not so occur. The partner apparently exercises the choice of whether to do B upon the occurrence of the participant's A.

In contrast, evidence relating to interaction strategy is presented in terms of probabilities of consequents. That is, given the

choice to do B or not-B after the occurrence of A, some partners may do B more than others. For example, upon activation of the speaker turn signal, some auditors may attempt to take the turn (leading to smooth exchanges) more frequently than others. Thus, the probability of the consequent (turn attempt) for one auditor may be .10, whereas for another auditor it may be .40, even though each attempt by either auditor is preceded by a turn signal (probability of antecedent = 1.00).

This example illustrates how there may be strong individual differences in the probability of a consequent in action sequences when the probability of an antecedent is essentially uniform across participants. When results of this sort are obtained, we would interpret the uniform antecedent probabilities as reflecting the organization of the observed interactions; the variations in consequent probabilities would be interpreted as reflecting participants' differences in interaction strategy within that organization.

Given a hypothesized organization for observed interactions, it seems natural that some studies of interaction strategy would investigate whether some participants more than others tend to exercise certain legitimate alternatives (such as acting to take the turn in the presence of a turn signal) or tend to violate certain rules (such as interrupting).

When the rule expresses an obligatory relationship between A and B—not providing for legitimate alternatives—we would expect B to follow A in virtually 100% of the occurrences of A (with possible allowances for rule violation and noise in the data). In this case, the probability of a consequent and the probability of an antecedent would both be close to 1.00. The ensuing discussion will be concerned only with action sequences involving legitimate alternatives. Obligatory sequences will not be further considered.

Strategy Effect of Organization Signals

Consider the case in which optimal results are obtained for an organization relationship between two actions (all B's are preceded by A's), and the relationship involves legitimate alternatives (not all A's are followed by B's). In this case, a certain type of strategy effect will be found: The occurrence of an A will raise the probability of a B from zero to some higher number. For example, if virtually all auditor attempts to take the speaking turn occur when the speaker turn signal is displayed, then we shall also find for every auditor that the speaker's displaying the turn signal increases the probability that the auditor will attempt to take the turn, when compared to those points at which there is no turn signal.

Of course, even when this sort of built-in strategy effect is found, there may be wide individual differences between participants in the probability of a B following an A. That is, upon display of a turn signal, some auditors may attempt to take the turn more than others. Nevertheless, all auditors will take the turn more when the turn signal is displayed than when it is not.

Thus, when the legitimate alternatives of doing B or not-B are involved, a specific type of strategy effect may be expected for all organization signals: The probability of B will be increased following the signal. But it should be noted that this same effect may be observed for other actions that regularly precede B, but that, for any reason, are not included in the hypothesized organization signal. How might such actions be excluded from an organization signal?

Further Criteria for Organization

Evidence for a hypothesized organization signal may not rest entirely on the associated probability of an antecedent. Other criteria may be invoked, depending on the nature of the hypothesized relationship and on the results of analyses. In some cases, a criterion will require that an action, A, precede all B's, but not precede instances of some other event, C. For example, the turn signal was hypothesized to precede smooth exchanges of the turn, but not instances of simultaneous turns in the conversation. That is, it was hypothesized that auditor attempts to take the turn when the turn signal is active would result in smooth exchanges of the turn and

that auditor attempts when the turn signal is not active would result in instances of simultaneous turns. Similarly, the speaker-state signal (Duncan & Fiske, 1977; Duncan & Niederehe, 1974) was hypothesized to occur at the beginnings of turn attempts by the auditor, but not at the beginnings of auditor back channels (Yngve, 1970), such as head nods and shakes and vocalizations such as "yeah," and "m-hm." The speaker-state signal was hypothesized to differentiate turn beginnings from auditor back channels. Of course, this sort of differentiation will not be a criterion for every signal, but it is useful when available.

Parsimony may also be used as a criterion. For example, an action, X, may not be incorporated as part of a hypothesized organization signal, O, if O already precedes virtually all instances of B, and the addition of X would serve merely to increase the number of displays of O. When an organization signal is hypothesized to have multiple cues, results may permit parsimony in the rules defining signal display. For example, the turn signal was hypothesized to have six distinct cues (described in more detail in the Results section). Strong results were obtained when a signal display was defined as a display of at least one cue, as opposed to more complex displays involving some specified combination of cues or some larger number of cues.

Thus, hypotheses on the organization of interaction will typically include criteria in addition to the probability of an antecedent. For this reason, an action that regularly precedes some subsequent Action B may not become part of the organization signal for B. It immediately follows that, because of these additional criteria, some actions may show the strategy effect described above for organization signals but not be part of any hypothesized signal, having been rejected on the basis of these additional criteria.

Strategy Signals

We are now in a position to consider the subject of this article: strategy signals. An action, S, will be considered a strategy signal in some observed interaction when it does not meet criteria set for the relevant organization signal, but it does show a distinctive relation to the probability of a subsequent action B. It also seems reasonable to expect that it show the high degree of consistency over participants in the interactions that was required for organization signals.

Evidence will be presented on three hypothesized strategy signals in the interactions we have observed. Although preliminary analyses suggest that additional strategy signals may be hypothesized in these interactions, space limitations prohibit their full description. In any event, such a listing is unnecessary for the purpose of introducing the notion and a general research approach.

Method

Analyses presented below were based on data drawn from videotapes of eight two-person conversations between adults. All participants were aware of the video camera and had given permission for the taping. Conversations are identified by the same numbering system used in Duncan and Fiske (1977). Interaction 1 was a psychotherapy intake interview between a male therapist about 40 years old and a female client in her early 20s. Interaction 2, an informal consultation about a client, was between the same therapist and another therapist, also about 40 years old; the two were good friends. Interaction 3 was between two male college students, recruited as they emerged from another psychological experiment; they were previously unacquainted and were paid $2 for their participation. Interaction 4 was between two female graduate students who worked as research assistants in the same office. They were continuing their discussion of shopping. Interactions 5–8 were between unacquainted professional-school students taking part in a larger study of interaction. These participants were instructed to have a conversation, to get acquainted, or to talk about anything else that interested them. Each of these participants was paid $3. These four interactions were between a male and a female. Interactions 1 and 2 each lasted 30 to 40 minutes, of which the first 19 minutes were transcribed and analyzed. All of the videotaped interaction was transcribed and analyzed in the remaining interactions. Interactions 3 and 4 were about 5 minutes long; and Interactions 5–8 were about 7.5 minutes long. Thus, about 78 minutes of interaction were analyzed.

Individual participants in each interaction are identified in terms of their interaction number and their sex (M,F). When the two participants are of the same sex, "a" and "b" will be appended to

their identifications. Thus, the participants in Interaction 1 are 1F and 1M; the participants in Interaction 2 are 2Ma and 2Mb.

For purposes of analysis, each interaction was subdivided into a series of units, defined in terms of the actions of the speaker. Briefly, a boundary of a unit of analysis was drawn at the onset of the first syllable following the end of a phonemic clause (Trager & Smith, 1957), during or immediately after which at least one of the following actions occurred: (a) a deviation in the intonation from an essentially level pattern (22| in the Trager–Smith system); (b) the utterance of a sociocentric sequence (Bernstein, 1962) such as "you know"; (c) the completion of a grammatical clause, involving a subject–predicate combination; (d) paralinguistic drawl (Trager, 1958) on the final syllable or stressed syllable of a phonemic clause; (e) termination of a hand gesticulation or the relaxation of a tensed hand position (e.g., a fist); (f) a decrease in paralinguistic pitch and/or loudness, either across an entire phonemic clause or during its final syllable or syllables; (g) an audible inhalation by the speaker; (h) an unfilled pause (Maclay & Osgood, 1959); (i) a false start (Maclay & Osgood, 1959); (j) turning the speaker's head direction toward the partner; and (k) a relaxation of the foot or feet from a strong dorsal flexion. Counts of occurrences and nonoccurrences of actions in the transcription were made using these units of analysis.

The data analyzed for this article had been transcribed previously at several different times. No interjudge agreement was tested for these particular data, because earlier analyses had yielded highly satisfactory results. For example, 96% agreement (Cohen's kappa = .80) was found for transcribing head direction on a syllable-by-syllable basis (Duncan & Fiske, 1977, p. 342; more detailed descriptions of the conversations and procedures are given in that book).

Results

Speaker's Head Direction

The speaker turn signal is defined as the display of at least one of six cues: the first five actions listed above in the drawing of units of analysis, plus one additional cue—a decrease of paralinguistic loudness or pitch on a sociocentric sequence. In the observed conversations, the turn signal was said to operate as follows: If the auditor acted to take the turn when the signal was active, the speaker was obliged to yield the turn. However, the auditor was not obliged to take the turn each time the signal was active; taking the turn in the presence of the signal is considered to be an option that the auditor may exercise.

In addition, a speaker gesticulation signal was hypothesized. This signal was composed of a single cue: one or both of the speaker's hands being engaged in gesticulation or in a tensed hand position. The gesticulation signal serves to inhibit any turn signal concurrently being displayed. That is, when the gesticulation signal is displayed concurrently with the turn signal, the auditor's attempts to take the turn are strikingly reduced.

Two criteria were used for evaluating the effectiveness of a possible turn signal: (a) The signal must precede a maximum number of smooth exchanges of the speaking turn in the observed conversations; (b) the signal must differentiate smooth exchanges of the turn from instances of simultaneous claimings of the turn by the two participants. Ideally, the signal would precede all instances of smooth turn exchanges and no instances of simultaneous turns. Notice that the signal is defined as the display of any one of its constituent cues. Therefore, each of these cues when occurring alone is evaluated by these two criteria.

Speaker's head direction was tested as a possible turn-signal cue. The cue was considered to be activated when the speaker's head turned toward the auditor. The potential head-direction cue was considered to be active from the moment of the actual head turning until the third boundary of a unit of analysis following the head turn (provided the head was still toward the auditor). Head direction was used in this case because it was not always possible to describe on our videotapes the direction of the speaker's gaze. However, head direction is taken as a surrogate for gaze direction; results for head direction are understood as most likely reflecting the effect of gaze.

Speaker's head direction was rejected as a possible turn cue for two reasons. First, it was not necessary. Virtually all smooth exchanges (251 out of 254; 98.8%) were preceded by at least one of the six turn cues described above. Second, inclusion of head direction would have substantially impaired the ability of the turn signal to differentiate

Table 1
Auditor Attempts to Take the Turn in Response to Speaker Turn-Signal Displays With and Without Concurrent Speaker Head-Direction Cue

Participant	No head-direction cue		Head-direction cue present		
	n[a]	Proportion of attempts	n[a]	Proportion of attempts	Ratio of proportions
1F	60	.116	75	.360	3.10
1M	13	.000	87	.367	—

6M	37	.108	71	.281	2.60
7F	62	.096	64	.265	2.76
7M	21	.095	52	.365	3.84
8F	6	.000	71	.281	—
8M	27	.111	49	.346	3.11
Total	437	.080	871	.289	3.61

Note. F = female; M = male; a and b = first and second members of a same-sex dyad.
[a] Number of units having a speaker turn-signal display, in the absence of a speaker gesticulation signal, and not followed by an auditor back channel; this number is the denominator for the proportion (e.g., for the first entry, first column, 7/60 = .116).

smooth exchanges from simultaneous turns. For example, in the eight conversations, there were 26 occurrences of simultaneous turns in which neither turn signal nor gesticulation signal was active. Nineteen of these occurrences (73%) were preceded by the potential head-direction cue. Thus, in the absence of the turn signal, the head-direction cue was associated with a large proportion of simultaneous turns in these data. When it occurred alone, the cue functioned quite poorly in differentiating smooth exchanges from simultaneous turns.

However, it is possible that the speaker's head direction has an effect on the auditor's subsequent response. Specifically, when the turn signal was active in the observed conversations, the auditor was more likely to attempt to take the turn when the speaker's head was toward the auditor than when it was not. (In these analyses, head direction was considered active for its full duration.) Table 1 shows data on the instances in which the turn signal was active and the gesticulation signal was not active. (The indicated participant is the speaker.) Rate of auditor attempts to take the turn when the head-direction cue was present is contrasted with that rate when the head-direction cue was not present. In this situation, 254 smooth exchanges and 33 simultaneous turns occurred. Each auditor showed a higher proportion of turn attempts when the speaker's head-direction cue was present. Summing across all participants, the auditor was about 3.6 times more likely to attempt to take the turn when the head-direction cue was present. In three cases, all of the auditor's turn attempts occurred when the head-direction cue was present. Although there was variation among the participants both in overall rate of turn attempts and in degree to which attempts were increased by the head-direction cue, the basic strategy-signal effect was present for each participant. (For all 16 participants showing an effect in the same

direction, $p < .0001$ in a two-tailed sign test.)

Speaker Smiling

Data on smiling were derived from the four conversations (2, 5, 6, 7) in which there was an appreciable number of smiles. In a recent study of these four conversations, Brunner (in press) found evidence that the beginnings of auditor smiles were distributed very much like auditor back channels (e.g., head nods and shakes and vocalizations such as "m-hm" and "yeah"). Like auditor back channels, auditor smile beginnings located at or just after the boundaries of units of analysis were systematically preceded by the speaker within-turn signal. Briefly, the latter signal is defined as the occurrence of at least one of two cues: completion of a grammatical clause by the speaker and the speaker's head facing in the auditor's direction.

In Duncan and Fiske (1977) this head-direction cue was considered to be deactivated three units of analysis after the speaker had turned his or her head toward the auditor. On the basis of Brunner's (in press) analyses of the original back-channel data, the head-direction cue was redefined as being present as long as the speaker's head was facing in the direction of the auditor. This new definition was also used for analyses of auditor smile beginnings.

We expected that within the organization of the observed conversations, speaker smiles would be part of a signal for auditor smile beginnings. However, the existing speaker within-turn signal was quite adequate in accounting for auditor smile beginnings: 39 of the 40 smile beginnings were preceded by the speaker within-turn signal. While the one remaining auditor smile was preceded by speaker smiling, there seemed little reason to redefine the signal on the basis of this single event. Further, including speaker smiling with various combinations of the two within-turn cues did not improve the statistical relationship between within-turn signal and subsequent auditor smile beginnings. Thus, it was concluded that speaker smiling was unnecessary to account for auditor smile beginnings in the observed conversations, and that speaker smiling did not add to the relationship between speaker signal and auditor smiling. Brunner's study led to the conclusions that auditor smiling was one form of auditor back channel and that the speaker within-turn signal marked the appropriate points for auditor smile beginnings located at or just after the boundaries of units of analysis, in the same manner that the signal functioned for the other, similarly placed auditor back channels previously studied.

The following hypothesis is advanced for speaker smiling as a strategy signal: When speaker smiling is present in addition to the speaker within-turn signal, the auditor is more likely to smile than when the speaker within-turn signal alone is present. That is, speaker smiling will increase the probability of a subsequent auditor smile beginning in response to the within-turn signal. Of course, auditor smiling is not mutually exclusive of other auditor back channels. The auditor might smile in conjunction with a head nod or "m-hm." The hypothesis merely states that there is an increased probability that smiling will be part of the response.

For each participant in the four conversations studied, Table 2 shows the percentage of displays followed by an auditor smile beginning (a) for within-turn-signal displays without smiling and (b) for within-turn-signal displays with concurrent speaker smiling. (In the table, the indicated participant is the speaker.) For each participant, the probability of auditor smiling is increased when speaker smiling is present ($p < .01$, two-tailed sign test).

Number of Turn Cues Displayed

Duncan and Fiske (1977) reported a positive, linear relationship between number of turn cues displayed conjointly by a speaker and the probability of a smooth exchange of the turn following the display. (This relationship was found only for turn-signal displays not accompanied by a gesticulation signal.) Two correlations between number of turn cues displayed and probability of smooth exchange were calculated, one pooling data

Table 2
Auditor Smiling in Response to Speaker Within-Turn-Signal Displays With and Without Concurrent Speaker Smiling

Participant	No speaker smiling		Speaker smiling		Ratio of proportions
	n[a]	Proportion of auditor smiling	n[a]	Proportion of auditor smiling	
2Ma	102	.009	1	1.000	—[b]
2Mb	273	.014	11	.090	6.42
5F	38	.053	8	.375	7.07
5M	34	.000	5	.600	—
6F	11	.090	20	.150	1.66
6M	16	.062	16	.250	4.03
7F	28	.178	19	.263	1.47
7M	19	.105	5	.400	3.80
Total	521	.030	85	.258	8.60

Note. M = male; F = female; a and b = first and second members of a same-sex dyad.
[a] Number of units having speaker within-turn-signal display and not followed by an auditor attempt to take the turn; denominator for proportion.
[b] Insufficient data.

from Conversations 1 and 2 and the other pooling data from Conversations 3 through 8. The correlations were .99 and .98, respectively. These pooled data suggest that the probability of a smooth exchange increases as the number of turn cues displayed increases. This relationship stems from interaction strategy, as it is based on the probability of a consequent: the probability of a smooth exchange following a cue display.

Table 3
Rate of Smooth Turn Exchanges as a Function of Number of Active Turn Cues (Gesticulation Signal Absent)

Participant	1 or 2 active turn cues		3 to 6 active turn cues		Ratio of proportions
	n	Proportion of smooth exchanges	n	Proportion of smooth exchanges	
1F	75	.160	58	.344	2.15
1M	70	.200	27	.555	2.77
2Ma	80	.050	31	.161	3.22
2Mb	40	.075	29	.241	3.21

7M	62	.225	7	.428	1.90
8F	60	.150	13	.538	3.58
8M	64	.203	9	.444	2.18
Total	945	.157	330	.318	2.02

Note. F = female; M = male; a and b = first and second members of a same-sex dyad.

Previous analyses had led to the rejection f number of turn cues displayed as part of ie definition of the turn signal within the rganization of the observed conversations. ince the display of any single cue was found o differentiate between smooth exchanges nd simultaneous talking, it was considered o constitute a display of the signal as a hole. In addition, it will be apparent that he reported correlations and the results be- ow are not simply a product of the strategy ffect of the turn signal. That strategy effect ould be to raise the probability of a smooth xchange from near zero following no turn ignal to some higher number following a ignal display.

Table 3 shows data for each participant in the eight conversations studied. Data for individual participants are insufficient to support analysis of each of the six data points (one through six cues). Therefore, two data points were calculated for each participant: the probability of a smooth exchange following (a) the display of one or two cues and (b) the display of three, four, five, or six cues. The data were divided between two and three cues because this division would permit sufficient observations in the two categories for each of the participants.

Table 3 shows that for 14 of the 16 participants, the probability of a smooth exchange following the display of one or two cues was lower than the probability of a smooth exchange following the display of three, four, five, or six cues. This result is significant at the .004 level (two-tailed test). These data disregard the presence or absence of the head-direction signal. When the data are analyzed only for instances in which the head-direction signal is present, the same results are obtained: 14 of the 16 participants showed the strategy-signal effect.

Discussion

The purposes of this article are to propose the strategy signal as a phenomenon of interest in face-to-face interaction, to suggest an approach to providing evidence supporting hypotheses of such phenomena, and to present evidence on three hypothesized strategy signals operating in some transcribed interactions.

We have suggested four criteria for hypothesizing an action to be a strategy signal: (a) that the strategy-signal action not meet criteria for hypothesizing it as an element in the relevant part of the organization of the interaction(s) studied; (b) that the action have an effect on the probability of occurrence of a subsequent action; (c) that this effect be highly consistent across the participants for which it is hypothesized; and (d) that the effect apply to action sequences involving legitimate alternatives—that the signal not be invariably followed by the subsequent action in question. By "effect" we mean a shift in the probability that the subsequent action will occur. We do not specify the exact nature or direction of this shift. Thus, it need not be of the kind described in the Results section.

Strategy Signals and Organization Signals

The strategy-signal criteria rely on the parallel distinctions between organization and strategy in interaction and between the probability of an antecedent and the probability of a consequent in analyses of action sequences. In general, we have identified the probability of an antecedent (the probability that A will precede B) with information on the organization or structure of interaction. This is because organization has to do with regularities in the placement of actions in interaction, given that they occur. More broadly, organization has to do with the appropriate placement of actions in the stream of interaction.

We have identified the probability of a consequent (the probability of B following A) with information on the strategy used in the interaction. This is because strategy is concerned with patterns of influence (or patterns of reaction) in interaction: one or more actions changing the probability that a subsequent action will occur.

Of course, hypothesizing A as an organization signal for B will almost certainly involve criteria in addition to the finding that A consistently precedes B. Investigators will

attempt to formulate the simplest and most effective definition of the hypothesized Signal A. And in some cases, the ability of the signal to differentiate different classes of action will be used as a criterion. An example would be the differentiating of smooth exchanges from simultaneous turns by the turn signal.

Of the four criteria proposed for hypothesizing a strategy signal, the last three seem relatively straightforward, whereas the first —that the action be excluded from the relevant part of the interaction organization— may bear further discussion. Strategy signals are seen as supplementing organization signals in describing interactions. If an action is an organization signal, we gain nothing by also labeling it as a strategy signal. Hence, a careful formulation of organization should precede the investigation of strategy signals. Furthermore, each organization signal has its own strategy effect. In the optimal case, when a given organization signal is not displayed, the probability of the consequent action associated with it is zero; but when the organization signal is displayed, the probability is some value above zero. This strategy effect of the organization signal stems from the fact that in the optimal case, the signal precedes all instances of the consequent action associated with it. That is, given the consequent action, the probability of the antecedent signal is 1.00. If an investigator finds, for example, that the occurrence of Action A raises the probability of a consequent Action B, A may be an organization signal or a strategy signal. Action A should be hypothesized as a strategy signal for B only after it has been rejected as part of an organization signal for B. This active rejection was part of the evaluation of each of the strategy signals hypothesized in the Results section.

This discussion indicates that the occurrence of a legitimate alternative, B, may be affected both by a preceding organization signal and by a preceding strategy signal. The hypothesis of a strategy signal enables the investigator to account for more of the variance in the occurrence of B than does an organization signal alone. However, as a legitimate alternative, the occurrence of B can never be entirely predicted on the basis of preceding actions. The partner is not in any sense "caused" to do B on the basis of preceding actions. Rather, in choosing to do B, the partner may be influenced to a greater or lesser extent by the participant's preceding organization and strategy signals.

Speaker's Head-Direction Signal

In the case of head direction and the turn signal, it is clear that the speaker's head being turned toward the auditor preceded many auditor attempts to take the turn; otherwise, the strategy-signal results (cast in terms of consequents) could not have been obtained. It was in differentiating smooth exchanges from simultaneous turns that head direction was markedly worse than the proposed turn-signal cues. Thus, even though the probability that the speaker's head direction precedes the auditor's turn attempt may be relatively high for many participants, head direction fails to meet the criteria set for turn-signal cues. The finding of a strong and consistent strategy effect, in the absence of the required organization effect, led us to propose a new interaction component: the strategy signal.

Despite the extensive literature on gaze direction (see Davis, 1972; Key, 1977; and Argyle & Cook, 1976, for references), there has not been intensive study of the relation of gaze direction to turn taking. Relevant exceptions would be an early study by Kendon (1967) and two more recent studies further exploring the phenomena Kendon described (Beattie, 1978; Rutter, Stephenson, Ayling, & White, 1978; see also an accompanying commentary by Kendon, 1978). Unfortunately, none of these studies provides data on the effect reported here: given a turn signal, an increased probability that the auditor will attempt to take the turn when the speaker is gazing. These investigations studied other parameters, such as the effect of speaker gaze on length of the pause between turns and the proportion of turn exchanges in which the speaker or auditor is looking or not looking.

The evidence presented here focuses on head direction (presumably gaze) with respect to a specific phenomenon: the exchange of speaking turns. Ellsworth and Langer (1976) take a broader perspective, suggesting that staring "elicits attention, arousal, and a sense of interpersonal involvement. The type of involvement inferred and the response perceived to be appropriate depend upon contextual cues" (p. 122). Although we are not certain that Ellsworth and Langer would consider staring to include the intermittent gazing typically found in conversations, we believe that the results presented here are entirely consistent with their hypothesis. The increased arousal resulting from speaker gaze may have prompted in part the higher rates of turn attempts by the auditor. From the perspective of Ellsworth and Langer, our results bear on some of the "contextual cues" relevant to the appropriate interpretation of gaze in the observed conversations.

Speaker Smiling Signal

As for smiling, the claim that speaker smiling increases the probability of auditor smiling is perhaps less surprising than the claim that speaker smiling is not part of an organization signal for auditor smiling in the observed conversations. Yet, in our conversations, it was true both that some speaker smiles were not reciprocated by the auditor and that some auditor smiles were not preceded by speaker smiles. (For an interesting account of auditor failure to reciprocate speaker smiling, see Rosenfeld, 1972.) Thus, the relationship between auditor and speaker smiling is not necessarily a simple one. In our conversations, the proposal to include auditor smiling within the more general auditor back-channel class of actions seems intuitively acceptable, is supported by a series of data analyses (Brunner, in press), and has the advantage of extending the province of the speaker within-turn signal (Duncan, 1974; Duncan & Fiske, 1977), while avoiding the necessity of hypothesizing an additional speaker organization signal.

Several studies have reported correlations between interacting subjects in the number or rate of smiles (Duncan & Fiske, 1977; Rosenfeld, 1966, 1967). Such correlations provide indirect support for the results reported here. But because data based on frequencies or rates do not contain information on the location of smiling in the interactions, they do not allow us to evaluate the degree to which smiles by a participant were actually reciprocated by the partner.

Number of Speaker Turn Cues as a Signal

As a strategy signal, number of turn cues is somewhat different from the two just discussed. Both head direction and smiling are actions that frequently precede their respective subsequent actions. In contrast, number of turn cues employs the same actions as the turn signal, but differs in the rule describing the way in which turn cues are combined. Effective results were obtained for the turn signal when number of turn cues displayed was ignored. The occurrence of any single cue constituted a full organization signal display. Number of turn cues displayed was considered and rejected as a possible element of the turn-signal definition. Analyses suggested that number was quite irrelevant to the criteria of (a) preceding smooth exchanges and (b) differentiating smooth exchanges from instances of simultaneous turns.

However, it seems additionally true for the conversations we observed that the probability of a smooth exchange increases in some manner as the number of turn cues increases. More specifically, for most participants the probability of smooth exchanges after the display of three, four, five, or six turn cues is greater than after the display of one or two turn cues.

Individual Differences

As mentioned in the Results section, Tables 1, 2, and 3 provide data on two types of strategy effects. On the one hand, there is evidence of consistency: Each speaker's head direction or smiling may be seen to change in the same direction the probability

of the relevant response by each auditor. This is the strategy-signal effect. On the other hand, variation between partners is evident in rates of response and in the degree to which that response is increased following the hypothesized strategy signal. This variation reflects the individual differences one may expect to find in interaction strategy, an area of research that extends well beyond strategy signals.

Generality of Results

How general are these strategy-signal results? We hold that generality in research of this sort is entirely an empirical matter, not a logical one. The organization and strategy signals discussed in this article are elements of social practices or conventions hypothesized to be operating in the observed interactions. The cultural boundaries of the use of these practices is an issue that must be determined empirically. A strict analogy would be work on language dialects. An investigator may interview one or more informants, gathering sufficient information to describe their dialect, but only dialect survey research can establish the geographical and demographic area in which the dialect is spoken. In dealing with social practices, we do not believe that it is appropriate to generalize to a postulated a priori domain, as is commonly done in some other types of behavioral research.

Nevertheless, we may cite circumstantial evidence that the strategy effects we report are not entirely confined to the conversations studied. With the exception of Conversations 2 and 4, the participants were unacquainted with each other prior to their interaction. The participants came from a rather wide variety of social and educational backgrounds and geographical areas. Although the settings were not completely natural, they were naturalistic and, hence, seem fairly representative of everyday interactions. In terms of the three dimensions of naturalness identified by Tunnell (1977), the behavior was natural and the treatment was also natural, because the stimuli for each participant were provided by the partner, and there were no experimental manipulations. For these reasons, findings from our studies may generalize more readily than results from contrived laboratory investigations or from responses in testing rooms.

Regardless of the domain to which a set of results applies, in the process of face-to-face interaction, a hypothesized organization implies strategy, and vice versa. Descriptions of strategy must be coordinated with descriptions of organization. Research on interaction requires careful examination of each side of an action sequence.

Editors Named for New *Journal of Personality and Social Psychology*

The Publications and Communications Board has named Melvin Manis, Ivan D. Steiner, and Robert Hogan to edit the *Journal of Personality and Social Psychology* (JPSP), which will appear in a new format in January 1980. The affiliations of the new editors are, respectively, University of Michigan and Veteran's Hospital, Ann Arbor; University of Massachusetts; and Johns Hopkins University. Manis will edit the section on ATTITUDES AND SOCIAL COGNITION, Steiner the section on INTERPERSONAL RELATIONS AND GROUP PROCESSES, and Hogan the section on PERSONALITY PROCESSES AND INDIVIDUAL DIFFERENCES.

An announcement on the restructuring of JPSP appeared on p. 668 of the June 1978 issue of JPSP. As indicated at that time, the three editors will work independently with separate groups of advisory editors. Their acceptances will appear as distinct sections in monthly issues of JPSP. Detailed descriptions of each section's coverage will be published in JPSP next month.

Manuscripts for JPSP are currently being received by Acting Editor Clyde Hendrick through March 31, 1979. As of April 1, 1979, authors should submit manuscripts to the appropriate section editor as follows:

ATTITUDES AND SOCIAL COGNITION

April 1 through June 15:

Melvin Manis

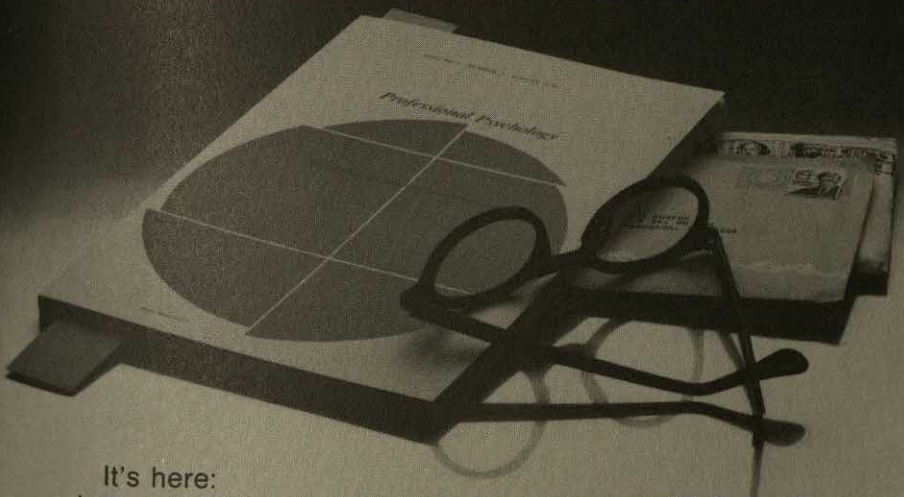
NOW: INFORMATION ABOUT THE LAW AND PSYCHOLOGY.



It's here:
Law and Professional Psychology. This special August 1978 issue of **Professional Psychology** brings you thirteen original articles full of fresh thought and constructive recommendations on the issues that vitally affect your day-to-day practice. You'll find precautions you may take to protect yourself as a professional and a plan for improving investigations of malpractice claims. Expert witness testimony, jury selection, civil commitment, confidentiality and privilege, minor's consent to treatment, and the use of psychological devices are critically examined.

Send your order today. And soon you'll receive this special issue.

Single copies of the issue are available for $5 each. All orders $25 or less must be prepaid. Make and send checks payable to:

American Psychological Association
Order Department
1200 17th Street, N.W.
Washington, D.C. 20036

Worchel & Cooper

Understanding Social Psychology

Revised Edition

Just Published

Stephen Worchel
University of Virginia

Joel Cooper
Princeton University

The **Revised Edition of Understanding Social Psychology** covers the traditional areas of social psychology—both theory and research. The authors show how social psychology can and cannot be utilized to better understand real events. They begin with a discussion of the individual—how attitudes are formed and socialization. They then focus on dyadic interaction—attribution, liking and love, helping, and aggression. Finally they discuss the individual in the group—conflict, conformity, leadership, and group effects on performance. The last chapter covers environmental psychology.

New to this edition is a glossary. A list of suggested readings is included at the end of the chapters. A **Student Study Guide (new for this edition)** by **Carl I. Greenberg,** University of Nebraska at Omaha is a supplemental learning device which provides an integrated summary.

Liebert & Spiegler

Personality: Strategies & Issues, Third Edition

Published in 1978

Robert M. Liebert
SUNY at Stony Brook

Michael D. Spiegler
Providence College

This volume provides a widely respected and highly readable introduction to the major strategies and issues in the psychological study of personality. The material is organized so that students can see clearly both the strengths and weaknesses of each viewpoint discussed. The four basic strategies covered are: 1) psychoanalytic, 2) dispositional, 3) phenomenological, and 4) behavioral.

Examination copies for adoption consideration available on request; please indicate course title and text presently used.

The Journal of Personality and Social Psychology publishes original reports of research, methodology, theory, criticism, and literature review in the fields of personality and social psychology of normal processes and populations. Submitted manuscripts should delineate an important question and provide a clear answer to it. In the case of research reports, this will often require demonstration that the reported results are generalizable beyond a single research setting. Consult the editorial in the January 1976 issue (Vol. 33, pp. 1–7) for a detailed statement of policies and instructions to authors.

Manuscripts: Submit manuscripts in quadruplicate, prepared according to the *Publication Manual of the American Psychological Association* (2nd ed.). Copies should be highly legible and will not be returned to authors unless they are original typewritten copies. Mail manuscripts according to instructions on pp. 468–469.

Required supplementary information: Manuscripts cannot be reviewed for publication unless the author provides supplementary information in the following categories: (a) a cover letter that indicates the relation (or the lack of relation) of the submitted manuscript to other papers by the same author(s) that are currently submitted, in press, or recently published; (b) one copy of each such related paper; (c) one copy of a statement of the procedures of the research reported in the submitted manuscript in sufficient detail to serve as a guide for conduct of an exact replication; and (d) one copy of the summary tables (e.g., correlation tables, analysis of variance summaries) for the *major* analyses reported. If it appears that the supplementary materials in categories (c) or (d) might be bulky, the author should exercise judgment and restraint in selecting what to send. It is not necessary to send supplementary material that repeats verbatim manuscript content.

After a manuscript is accepted, authors will be expected to provide assurance that their data are available in unanalyzed form for reanalyses by other investigators and that their research procedures were consistent with the American Psychological Association's published principles of research ethics, except insofar as may be detailed otherwise in the manuscript.

Copyright and Permission: All rights reserved. Written permission must be obtained from the American Psychological Association for copying or reprinting text of more than 500 words, tables, or figures. Permission is normally granted contingent upon like permission of the author, inclusion of the APA copyright notice on the first page of reproduced material, and payment of a fee of $10 per page, table, or figure. Abstracting is permitted with credit to the source. Permissions and fees are waived for authors who wish to reproduce their own material for personal use; fees only are waived for authors who wish to use their own material commercially. Permission and fees are waived for the photocopying of isolated articles for nonprofit classroom or library reserve use by instructors and educational institutions. Libraries are permitted to photocopy beyond the limits of U.S. copyright law: (1) those post-1977 articles with a code at the bottom of the first page, provided the per-copy fee indicated in the code is paid through the Copyright Clearance Center, P.O. Box 765, Schenectady, NY 12301; (2) pre-1978 articles, provided that the per-copy fee stated in the Publishers' Fee List is paid through the Copyright Clearance Center, P.O. Box 765, Schenectady, NY 12301. Address requests for reprint permission to the Permissions Office, APA, 1200 Seventeenth Street, N.W., Washington, D.C. 20036.

Subscriptions: Subscriptions are available on a calendar year basis only (January through December). Nonmember rates for 1979: $60 domestic, $64 foreign, $6 single issue. APA member rate: $20. Write to Subscription Section, APA.

Change of Address: Send change of address notice and a recent mailing label to the attention of the Subscription Section, APA, 30 days prior to the actual change of address. APA will not replace undelivered copies resulting from address changes; journals will be forwarded only if subscribers notify the local post office in writing that they will guarantee second-class forwarding postage.

Reprints: Authors may order reprints of their articles from the printer when they receive proofs.

Back Issues and Back Volumes: For information regarding back issues or back volumes write to Order Department, APA.

Microform Editions: For information regarding microform editions write to any of the following: Johnson Associates, Inc., P.O. Box 1017, Greenwich, Connecticut 06830; University Microfilms, Ann Arbor, Michigan 48106; or Princeton Microfilms, Princeton, New Jersey 08540.

Published monthly in one volume per year by the American Psychological Association, Inc., 1200 Seventeenth Street, N.W., Washington, D.C. 20036. Printed in the U.S.A. Second-class postage paid at Washington, D.C., and at additional mailing offices.

Attitudes Cause Behaviors: A Cross-Lagged Panel Analysis

Lynn R. Kahle
University of Michigan (Ann Arbor)

John J. Berman
University of Nebraska—Lincoln

Cross-lagged panel correlations were computed between attitudes and behaviors with respect to college students' ratings of four issues: Jimmy Carter's presidential candidacy, Gerald Ford's candidacy, drinking, and religion. For all four issues, attitudes showed causal predominance over behaviors. These results are interpreted as supporting McGuire's views on the attitude–behavior relationship but as being contrary to Wicker's situational determinism and self-perception theory. Kelman's view of reciprocal causation between attitudes and behaviors is also discussed.

The question of the causal relationship between personal factors such as attitudes, on the one hand, and behaviors, on the other, has a long and illustrious history. William James (1884) was one of the first psychologists to raise the question: "Common sense says, we lose our fortune, are sorry and weep; we meet a bear, are frightened and run; we are insulted by a rival, are angry and strike. The hypothesis here to be defended says that this order of sequence is incorrect" (p. 190).

At the most basic level, one could assume four types of relationships between attitudes and behavior: Attitudes cause behaviors; behaviors cause attitudes; there is reciprocal causation; or the two are causally unrelated. Each of these positions has a contemporary proponent. McGuire (1976) has argued that attitudes generally lead to behavior. D. Bem (1972) has proposed that when internal cues are weak or ambiguous, situationally determined behaviors will lead to attitudes. Kelman (1974) maintains that attitudes guide behaviors but that behaviors also guide attitudes. Wicker (1969) reviewed a number of studies on the relationship between attitudes and behaviors and concluded that "taken as a whole, these studies suggest that it is considerably more likely that attitudes will be unrelated or only slightly related to overt behaviors than that attitudes will be closely related to actions" (p. 65). Hence, the basic

A version of this article was presented at the annual meeting of the Midwestern Psychological Association, Chicago, May 6, 1978. A preliminary report of these data is also contained in the first author's doctoral dissertation (Kahle, 1977). He gratefully acknowledges the aid of his dissertation committee cochairmen, Monte M. Page and John J. Berman, and committee members Richard A. Dienstbier, Harry P. Shelley, and Bruce Dennis Sales. Also deserving of special thanks is David Kenny for his helpful comments on cross-lagged panel correlation.

Requests for reprints should be sent to Lynn R. Kahle, Room 5130, Institute for Social Research, University of Michigan, Ann Arbor, Michigan 48106.

question that James raised has yet to be resolved. Nevertheless, the results of many laboratory studies supporting Bem and/or Wicker have created some degree of pessimism about the predictive utility of attitudes (cf. McGuire, 1976).

Although discriminating between these four hypotheses in terms of which is more accurate is important for attitude theory and research, it has been difficult to contrast these hypotheses within one laboratory study, in part because, typically, only attitudes or only behaviors are used as independent variables. Thus, the reviewer must rely on only cross-study comparisons to reach any conclusions. This reliance is always risky, because of the numerous differences unrelated to theory that exist between different studies. Furthermore, random assignment of individuals to attitudes may be misleading, since the laboratory-induced attitudes either may be trivial or may interact with prior attitudes.

An entirely new methodology may be necessary before we can progress to a new level of understanding empirically the relationship between attitudes and behaviors. Kenny (1975) has developed a different methodology, cross-lagged panel correlation, which may prove useful for a better understanding of these issues. This article reports on the results of a cross-lagged panel correlation study of the relationship between attitudes and behaviors.

Method

Subjects

The 463 introductory psychology students who filled out questionnaires at both of the times they were administered were the subjects for this research. Each subject was asked questions about the candidacy of Jimmy Carter and Gerald Ford for the presidency, about drinking, and about religion. After deletion of subjects for whom at least one data point was missing for a particular set of variables, the sample size for the political issues was 362, for the drinking issues was 326, and for the religion issues was 394.

Cross-Lagged Panel Correlation

Because some readers may be unfamiliar with cross-lagged panel correlation (CLPC), a brief overview of the method is given here. A comprehensive overview has been given by Kenny (1975).

CLPC is a quasi-experimental design useful for testing causal hypotheses from correlational data. Within a panel (longitudinal) study, there may be both *panel variables,* which are relatively fluctuating (although they should be reliably measured) variables measured at more than one time, and *control variables,* which are relatively stable variables measured at only one point in time (e.g., sex). In the simplest case in which CLPC can be used, two panel variables, A and B, are measured at two separate times, Time 1 and Time 2. There are six possible correlations that can be computed with these data: two synchronous correlations (r_{A1B1} and r_{A2B2}), two autocorrelations (r_{A1A2} and r_{B1B2}), and two cross-lagged correlations (r_{A1B2} and r_{A2B1}). When the cross-lagged correlations are different, as indicated by a Pearson-Filon z test for differences between correlated correlations (Kenny, 1975), and when various other assumptions have been satisfied, one may state that there is a causal relationship between the variables. For example, if $r_{A1B2} > r_{B1A2}$, if both are positive, and if other assumptions have been satisfied, one may state that increases in A cause increases in B, as opposed to stating that increases in B cause increases in A.

In true experiments, randomization is used to rule out the plausibility of spuriousness (third-variable effects) as an alternative explanation to experimental effects. CLPC rules out spuriousness as an alternative explanation to research effects by means of two assumptions about the data: synchronicity and stationarity. *Synchronicity* means that the scores that comprise the synchronous correlations measure processes that occurred at the same time, and *stationarity* means that the causal structure for the variables did not change over time. Kenny (1973) has formulated a mathematical model that given synchronicity, stationarity, and spuriousness, the cross-lagged correlations do not differ significantly.

Stationarity may be of three types: perfect stationarity, proportional stationarity, or quasi stationarity. When the structural equation of the variables does not change over time, perfect stationarity is obtained. A lack of change in synchronous correlations is consistent with perfect stationarity. Proportional stationarity refers to the case in which the structural equations of the variables change by some proportional constant over the time lag. Quasi stationarity refers to the case in which the structural equation of each variable changes over time by a constant unique for each variable (Kenny, 1975). The implication of the assumption of quasi stationarity is that the synchronous correlations would equal each other if corrected for attenuation due to measurement unreliability. If a set of data meets the assumptions of quasi stationarity but not perfect or proportional stationarity, it is necessary to adjust the cross-lagged correlations prior to testing for spuriousness. This adjustment is necessary because variables with decreasing reliability would tend to appear to be causes, and variables with increasing reliability would tend to appear to be effects. It is

possible to test the various assumptions of stationarity statistically (Kenny, 1973, 1975, Note 1) when one has more than two panel variables.

Advantages and Limitations of CLPC

CLPC has an obvious advantage over traditional correlations in that it can be used for causal inferences. It also has some advantages over traditional analysis of variance designs, since it does not necessarily assume randomization and variable manipulation. As a correlational design, it has the further advantage that one need not discriminate between independent and dependent variables a priori. In the attitude–behavior controversy, for example, both attitudes and behaviors could have equal probability of showing up as a cause or as an effect in a CLPC design.

Although CLPC has several advantages over analysis of variance designs, it also has several limitations or weaknesses in comparison to analysis of variance designs. The first limitation is that CLPC is a low-power statistical procedure. Because of this low power, the alpha level for this research was set at .1 for the Pearson-Filon tests of differences between cross-lagged correlations.

Another problem with CLPC is specifying the appropriate time lag. Nothing about the procedure specifies what the appropriate time lag might be with respect to a particular research question. Quite often social science theory also fails to guide researchers to an appropriate time lag. This problem also exists in other longitudinal research and in laboratory research. In the area of attitude change, for example, McGuire (1960) argued that laboratory cognitive-consistency manipulations may not show their full effect for a week. The time lag for noticeable attitude change in the absence of an experimental manipulation is probably often much longer. One possible solution to this problem in the ideal case would be to sample numerous time lags. In the present study, the time lag was identical for all issues, but the issues did differ with respect to the pace at which they were expected to change. During an election year, one may assume that political perspectives are under a great deal of pressure to change, whereas religious and drinking perspectives may tend to change more slowly. Further advantages and limitations of CLPC are given elsewhere (Kahle, 1977; Kenny, 1975, in press).

Hypotheses

In this study, two panel variables, attitude and behavior, were measured for four issues—Jimmy Carter's presidential candidacy, Gerald Ford's candidacy, drinking, and religion.[1] It was hypothesized that, for each of the four issues, attitudes would lead to behaviors.

Diary No.....
Date.....

Materials

The items for all of the panel variables were developed specifically for the purposes of this research, in order to test the constructs of interest: attitudes and behaviors. An initial pool of items was generated by consulting some previous tests of the relevant issues (e.g., Manson, 1963; Robinson & Shaver, 1973) and by using the authors' knowledge of the issues. These 89 items were pilot tested on a group of 41 introductory psychology students. Topics of concern in this pilot study included whether scale points on the questionnaire were appropriately spaced and whether the questionnaire contained demand characteristics or other factors that could potentially bias the responses. Tests of internal consistency (Burns, Note 2) generally guided decisions about what items would be included in the variables for the actual research, but in some cases intuitions overruled psychometrics, because the Republican party had not yet selected a presidential candidate at the time of the pilot study.

Each subject in the actual research responded to all of the panel-variable items twice and all of the control-variable items once. Before any CLPC analyses were completed, the items for each panel variable were analyzed to test whether they were detracting from the internal consistency of the variable. Three political behavior items were eliminated because they detracted from the internal consistency of the variable that they were intended to represent. The eliminated items were ones that had highly skewed distributions and very small variances (e.g., "How many times in the past 14 days have you put up a sign or bumper sticker supporting Jimmy Carter?").

Subjects rated each attitude item on a scale ranging from strongly agree (1) to strongly disagree (9). For the behavior items, subjects were asked how many times in the past 14 days they had engaged in the activity mentioned in the item. The items for each variable (i.e., attitude and behavior) within each issue were summed to obtain one score for each variable.

Table 1 presents an example of an item from each set of questions used to measure the panel variables. The item that correlated most highly with the total score for all of the other items in each panel-variable scale was selected for inclusion in Table 1.

The scales appear to be adequate psychometrically. Table 2 presents two measures of internal consistency, Cronbach's (1951) alpha and Wollin's index of single-factoredness (Burns, Note 2), for each panel variable from both times of measurement. Each

---

[1] A third panel variable, stimulus condition self-selection, was also included in Kahle (1977). This third panel variable was used in the data reported here for tests of stationarity, since it is necessary to have at least three panel variables to test for stationarity.

Table 1
Representative Item From Each Set of Questions

Variable	Item
Carter issues	
Attitude	I strongly support Jimmy Carter for president. (5)
Behavior	How many times in the past 14 days have you made a favorable comment about Jimmy Carter? (7)
Ford issues	
Attitude	I strongly support Gerald Ford for president. (5)
Behavior	How many times in the past 14 days have you made a favorable comment about Gerald Ford? (7)
Drinking issues	
Attitude	I like to drink. (14)
Behavior	How many times in the past 14 days have you had at least one drink? (9)
Religion issues	
Attitude	Being active in church is important. (9)
Behavior	How many times in the past 14 days have you prayed in private?
	How many times in the past 14 days have you been with people from your church? (9)

Note. The number in parentheses after each item is the total number of items in that item's variable scale.

variable was also correlated with the Bem Sex Role Inventory (BSRI) Social Desirability Scale (S. Bem, 1974). All correlations were quite low, with the mean $r^2 = .01$ and the median $r = -.008$.

A number of control variables were measured along with the panel variables. At Time 1, subjects provided demographic information and completed the Bem Sex Role Inventory. At Time 2, subjects answered questions about their religious affiliation, interest in the presidential campaign, self-perceptions of the importance of their attitudes ("Among all of your attitudes, how important are your attitudes toward alcoholic beverages?"), and their attitudinal entailment ("How many attitudes do you have which are related to your attitudes toward alcoholic beverages?") (Kahle, in press). A principal-components factor analysis with a varimax rotation was performed on the Bem Sex Role Inventory,[2] and all items with a factor loading greater than .55 after rotation were summed for each factor with an eigenvalue greater than 1.6. These factors were used as control variables.

The purpose of control variables in CLPC is to increase the stationarity of the data (Kenny, 1975). Three criteria were employed to select which of the many control variables would in fact be used for the cross-lagged panel analysis. To be included, a control variable had (a) to account for some noticeable variance of several of the panel variables within a given analysis (Kenny, 1975), (b) to have some theoretical relevance, and (c) not to reduce sample size excessively because of missing data.

Control variables for each set of panel variables were partialed from all panel variables in that set before any cross-lagged panel tests were performed (Kenny, Note 1). The control variables that met all three of the above criteria for inclusion with respect to political variables included independence (a factor from the Bem Sex Role Inventory), hometown size, importance of political attitudes, and number of debates observed. The drinking control variables were year in college, sex, importance of drinking, and entailment (Kahle, in press) of drinking. The religion control variables were hours per week of work during the school year, extent of self-support for education, and importance of religion.

Procedure

The potential pool of respondents was students enrolled in a large introductory psychology course.

[2] Other researchers at the same university were administering the BSRI to the same subjects for different purposes. Because the BSRI Social Desirability Scale was judged to be psychometrically adequate and in order to avoid overwhelming the subjects with yet another rating scale, a more traditional measure of social desirability was not administered. Given the availability of the data from the rest of the BSRI, it was decided to use those data, too. S. Bem's original masculinity, femininity, and androgyny scores did not account for major amounts of variance in the attitude and behavior data here. In general, the factor analysis showed about the same factor structure that one would expect based on S. Bem's (1974) reported internal consistency measures, with some minor qualifications probably due to differences in subject populations.

At the first meetings of this class, the instructors introduced the course and then asked the students to complete a "Background Information Questionnaire." Students attended these sessions in groups of approximately 75 during the week of August 30, 1976. The date was less than 2 weeks after the Republican National Convention had nominated Gerald Ford.

The students were offered half an hour of research participation credit toward their 3-hour requirement to complete the questionnaire again during the last complete week prior to the presidential election (October 25, 1976). Thus, the time lag was selected to be appropriate for the political issues, and it may or may not have been appropriate for the drinking issues or the religion issues.

Results

Table 3 displays the results from the tests of differences among the cross-lagged correlations. For all four issues, the "attitudes lead to behaviors" hypothesis was significantly supported in the direction predicted.

For those readers familiar with CLPC, several additional details may be useful in interpreting Table 3. All sychronous correlations and autocorrelations were positive and were larger than .30. The degrees of freedom for the tests were 360 for the Carter variables, 360 for the Ford variables, 392 for the religion variables, and 324 for the drinking variables.

Table 2
Internal Consistency of Scales: Cronbach's Alpha[a] and Wollin's Index[b] of Single-Factoredness

Variable	Cronbach's alpha		Wollin's index	
	Time 1	Time 2	Time 1	Time 2
Carter issues				
Attitude	.82	.86	.88	.90
Behavior	.72	.68	.92	.93
Ford issues				
Attitude	.84	.86	.94	.93
Behavior	.84	.75	.97	.92
Drinking issues				
Attitude	.90	.92	.85	.91
Behavior	.92	.89	.93	.95
Religion issues				
Attitude	.85	.86	.94	.96
Behavior	.79	.80	.82	.82

Table 3
Attitude–Behavior Cross-Lagged Correlation Test Results

Issue	r_{A1B2}	r_{B1A2}	Difference	z^a
Carter's candidacy	.53	.18	.35	6.29**
Ford's candidacy	.57	.13	.44	7.73**
Religion	.57	.49	.07	1.84*
Drinking	.58	.48	.10	2.20**

[a] Pearson-Filon test for the differences between correlated correlations, following Kenny (1975).
* $p < .1$.
** $p < .05$.

Only the political data have been corrected to meet the assumptions of quasi stationarity. This correction was statistically necessary (probably because the salience of politics intensified during the time lag), in order to rule out changing reliability as an alternative explanation to obtained effects. Uncorrected variables with increasing reliability could otherwise spuriously appear to be effects (Kenny, 1975). The disadvantage of this correction is that it may increase sampling error and thereby make the Pearson-Filon test more approximate. In the present case, in which the political data do not yield borderline results, the approximate nature of the significance test is probably not a problem. For the religion data, the assumption of perfect stationarity was tenable, and for the drinking data, the assumption of proportional stationarity was tenable; thus, it was unnecessary to adjust the religion and drinking data to meet the assumptions of quasi stationarity.

Kenny's weights (Note 1) for estimating the relative sampling error for the Carter, Ford, drinking, and religion data were, respectively, 2.2, 1.9, 8.2, and 7.9. In general, weights of less than 1 should not be interpreted, and weights between 1 and 2 should be interpreted with caution (Kenny, Note 1). These weights, then, imply that a slight amount of caution is called for in interpreting the Ford data. Kenny's (Note 1) overall reliability (communality) ratios for the Carter, Ford, drinking, and religion data

were 1.178, 1.264, 1.044, and 1.008, respectively. Reliability ratios greater than 1 indicate increasing reliability, whereas ratios less than 1 indicate decreasing reliability. Here reliabilities increased slightly. The larger of the cross-lagged correlations tended to be slightly larger than the synchronous correlations. Since Kenny (1975) argues that a cross-lag larger than the synchronous correlations is indicative of a causal effect, this result provides additional (although minor) evidence consistent with the inferences.

Discussion

The results are straightforward. Attitudes had causal predominance over behaviors for all four issues. The weak or nonexistent relationship between attitudes and behaviors that one would expect in the absence of extensive situational information, if one were to accept Wicker's (1969) analysis, was not supported here. This study provided ample evidence for the utility of assuming that attitudes lead to behaviors. In all cases the correlation between attitudes at Time 1 and behaviors at Time 2 was greater than .5.

This study clearly implies that knowledge of attitudes has an important degree of predictive utility. For the politicians, theologians, and alcoholism therapists who may be interested in knowing whether their efforts to change attitudes will help them to achieve their ultimate goals of changing behaviors, the answer appears to be yes. Furthermore, knowledge about present attitudes will help predict future behaviors (in the absence of change). The pessimism about the predictive utility of attitudes is to some extent diminished. With McGuire (1976) we can call into question Wicker's emphasis:

> It is currently fashionable to stress situational determinants of behavior and question whether there are any personal determinants at all (Endler and Hunt, 1968; Mischel, 1973; Alker, 1972; Endler, 1973; [D.] Bem and Allen, 1974). I might seem, therefore, to be violating the current orthodoxy in the yin and yang of conventional wisdom on this issue when I stress the role of attitudes in predicting behaviors that purportedly are determined primarily by situational factors. (p. 9)

The attitude–behavior cross-lagged correlation differences also contradict at least the starting point of self-perception theory (D. Bem, 1972). Although these results do not "disprove" self-perception theory, since Bem theorizes that behaviors will lead to attitudes only "to the extent that internal cues are weak, ambiguous, or uninterpretable" (p. 2), the results do suggest that with respect to topics such as politics, religion, and drinking, this qualification to self-perception theory may need to be invoked more often than the theory itself. And with respect to renditions of self-perception theory that minimize the importance of this qualification (e.g., Kleinke, 1978), the present data are quite damaging. The preponderance of attention given to artificial laboratory studies during the past several decades of attitude research may have distorted our ability to discriminate between major and minor naturally occurring processes involved in attitude change. By way of qualification, however, it is important to note that the data reported here have at best only slight implications concerning issues such as the heuristic utility of self-perception theory in areas such as attribution research. Even if the starting point of a theory is called into question, the total theory may nevertheless make other valuable contributions (Kahle, 1978).

Kenny's (1975) contribution in developing CLPC may have as many implications for theory as it has methodological implications, because of the way it allows researchers to ask questions. In CLPC research it is not necessary to determine irrevocably which of several factors is causal prior to conducting the research. Kenny's methodology also allows the investigation of reciprocal causation and cyclical causation (which may be characteristic of attitudes and behaviors) through the sampling of multiple time lags.

With respect to reciprocal causation, the present data do not suggest that behaviors are causally void. Certainly, a number of laboratory studies suggest that in certain circumstances, behaviors can lead to attitudes. A particularly fruitful area to explore in this vein may be the differences in attitudes about objects, the typical topic of interest, and attitudes about behaviors (Fishbein & Ajzen, 1974). Even when behaviors lead to attitudes, however, it may be that the re-

sultant attitudes themselves will lead to new behaviors (Kelman, 1974). McGuire's (1976) discussion of reciprocal causation is especially sophisticated.

Although the results of the present study clearly show that attitudes have causal predominance over behaviors on these issues, a few words of caution are in order. In some cases, a difference in levels of specificity between attitudes and behaviors may lead to inconsistency (Weigel, Vernon, & Tognacci, 1974). People may often hold contradictory attitudes (Kelman, 1974). Attitudes may be better predictors of groups of behaviors than of specific behaviors (Fishbein & Ajzen, 1974). What researchers view as attitude–behavior consistency may not be what research subjects view as consistency (Bernstein & Kahle, Note 3; cf. also Bem & Allen, 1974). And, of course, other things besides attitudes influence behaviors.

Egocentric Biases in Availability and Attribution

Michael Ross and Fiore Sicoly
University of Waterloo, Waterloo, Canada

Five experiments were conducted to assess biases in availability of information in memory and attributions of responsibility for the actions and decisions that occurred during a previous group interaction. The subject populations sampled included naturally occurring discussion groups, married couples, basketball teams, and groups assembled in the laboratory. The data provided consistent evidence for egocentric biases in availability and attribution: One's own contributions to a joint product were more readily available, that is, more frequently and easily recalled; individuals accepted more responsibility for a group product than other participants attributed to them. In addition, statements attributed to the self were recalled more accurately and the availability bias was attenuated, though not eliminated, when the group product was negatively evaluated (Experiment 2). Finally, when another participant's contributions were made more available to the individual via a selective retrieval process, the individual allocated correspondingly more responsibility for the group decisions to the coparticipant (Experiment 5). The determinants and pervasiveness of the egocentric biases are considered.

One instance of a phenomenon examined in the present experiments is familiar to almost anyone who has conducted joint research. Consider the following: You have worked on a research project with another person, and the question arises as to who should be "first author" (i.e., who contributed more to the final product?). Often, it seems that both of you feel entirely justified in claiming that honor. Moreover, since you are convinced that your view of reality must be shared by your colleague (there being only one reality), you assume that the other person is attempting to take advantage of you. Sometimes such concerns are settled or prevented by the use of arbitrary decision rules, for example, the rule of "alphabetical priority"—a favorite gambit of those whose surnames begin with letters in the first part of the alphabet.

We suggest, then, that individuals tend to accept more responsibility for a joint product than other contributors attribute to them. It is further proposed that this is a pervasive phenomenon when responsibility for a joint venture is allocated by the participants. In many common endeavors, however, the participants are unaware of their divergent views, since there is no need to assign "authorship"; consequently, the ubiquity of the phenomenon is not readily apparent. The purpose of the current research was to assess whether these egocentric perceptions do occur in a variety of settings and to examine associated psychological processes.

In exploring the bases of such differential perceptions, we are not so naive as to suggest that intentional self-aggrandisement never occurs. Nonetheless, it is likely that perceptions can be at variance in the absence of deliberate deceit; it is from this perspective that we approach the issue.

To allocate responsibility for a joint endeavor, well-intentioned participants presum-

This research was supported by a Canada Council grant to the first author. We are grateful to the following people for their comments on earlier versions of this article: Dick Bootzin, Leslie McArthur, Hildy Ross, Lee Ross, Shelley Taylor, Amos Tversky, and Mark Zanna. We thank Vicky Vetere for collecting the data in Experiment 5.

ably attempt to recall the contributions each made to the final product. Some aspects of the interaction may be recalled more readily, or be more available, than others, however. In addition, the features that are recalled easily may not be a random subset of the whole. Specifically, a person may recall a greater proportion of his or her own contributions than would other participants.

An egocentric bias in availability of information in memory, in turn, could produce biased attributions of responsibility for a joint product. As Tversky and Kahneman (1973) have demonstrated, people use availability, that is, "the ease with which relevant instances come to mind" (p. 209), as a basis for estimating frequency. Thus, if self-generated inputs were indeed more available, individuals would be likely to claim more responsibility for a joint product than other participants would attribute to them.

There are at least four processes that may be operating to increase the availability of one's own contributions: (a) selective encoding and storage of information, (b) differential retrieval, (c) informational disparities, and (d) motivational influences.

Selective Encoding and Storage

For a number of reasons, the availability of the person's own inputs may be facilitated by differential encoding and storage of self-generated responses. First, individuals' own thoughts (about what they are going to say next, daydreams, etc.) or actions may distract their attention from the contributions of others. Second, individuals may rehearse or repeat their own ideas or actions; for example, they might think out their position before verbalizing and defending it. Consequently, their own inputs may receive more "study time," and degree of retention is strongly related to study time (Carver, 1972). Third, individuals' contributions are likely to fit more readily into their own cognitive schema, that is, their unique conception of the problem based on past experience, values, and so forth. Contributions that fit into such preexisting schemata are more likely to be retained (Bartlett, 1932; Bruner, 1961).

Differential Retrieval

The availability bias could also be produced by the selective retrieval of information from memory. In allocating responsibility for a joint outcome, the essential question from each participant's point of view may be, "How much did *I* contribute?" Participants may, therefore, attempt to recall principally their own contributions and inappropriately use the information so retrieved to estimate their *relative* contributions, a judgment that cannot properly be made without a consideration of the inputs of others as well.

Informational Disparities

There are likely to be differences in the information available to the contributors that could promote egocentric recall. Individuals have greater access to their own internal states, thoughts, and strategies than do observers. Moreover, participants in a common endeavor may differ in their knowledge of the frequency and significance of each other's independent contributions. For example, faculty supervisors may be less aware than their student colleagues of the amount of time, effort, or ingenuity that students invest in running subjects, performing data analyses, and writing preliminary drafts of a paper. On the other hand, supervisors are more cognizant of the amount and of the importance of the thought, reading, and so on that they put into the study before the students' involvement begins.

Motivational Influences

Motivational factors may also mediate an egocentric bias in availability. One's sense of self-esteem may be enhanced by focusing on, or weighting more heavily, one's own inputs. Similarly, a concern for personal efficacy or control (see deCharms, 1968; White, 1959) could lead individuals to dwell on their own contributions to a joint product.

The preceding discussion outlines a number of processes that may be operating to render one's own inputs more available (and more likely to be recalled) than the contributions of others. Consequently, it may be dif-

ficult to imagine a disconfirmation of the hypothesis that memories and attributions are egocentric. As Greenwald (Note 1) has observed, however, the egocentric character of memory "is not a necessary truth. It is possible, for example, to conceive of an organization of past experience that is more like that of some reference work, such as a history text, or the index of a thesaurus" (p. 4). In addition, we were unable to find published data directly supportive of the hypothesized bias in availability. Finally, recent developments in the actor–observer literature seem inconsistent with the hypothesis that memories and attributions are egocentric. Jones and Nisbett (1971) speculated that actors are disposed to locate the cause of their behavior in the environment, whereas observers attribute the same behavior to stable traits possessed by the actors. Though a variety of explanations were advanced to account for this effect (Jones & Nisbett, 1971), the recent emphasis has been on perceptual information processing (Storms, 1973; Taylor & Fiske, 1975). The actor's visual receptors are aimed toward the environment; an observer may focus directly on the actor. Thus, divergent aspects of the situation are salient to actors and observers, a disparity that is reflected in their causal attributions. This proposal seems to contradict the thesis that actors in an interaction are largely self-absorbed.

Two studies offer suggestive evidence for the present hypothesis. Rogers, Kuiper, and Kirker (1977) showed that trait adjectives were recalled more readily when subjects had been required to make a judgment about self-relevance (to decide whether each trait was descriptive of them) rather than about a number of other dimensions (e.g., synonymity judgments). These data imply that self-relevance increases availability; however, Rogers et al. did not contrast recall of adjectives relevant to the self with recall of adjectives relevant to other people—a comparison that would be more pertinent to the current discussion. Greenwald and Albert (1968) found that individuals recalled their own arguments on an attitude issue more accurately than the written arguments of other subjects. Since the arguments of self and other were always on opposite sides of the issue, the Greenwald and Albert finding could conceivably reflect increased familiarity with, and memory for, arguments consistent with one's own attitude position rather than enhanced memory for self-generated statements (although the evidence for attitude-biased learning is equivocal, e.g., Greenwald & Sakumura, 1967; Malpass, 1969).

We conducted a pilot study to determine whether we could obtain support for the hypothesized bias in availability. Students in an undergraduate seminar were asked to estimate the number of minutes each member of the seminar had spoken during the immediately preceding class period. An additional 26 subjects were obtained from naturally occurring two-person groups approached in cafeterias and lounges. The participants in these groups were asked to estimate the percentage of the total time each person had spoken during the current interaction.

It was assumed that subjects would base their time estimates on those portions of the conversation they could recall readily. Thus, if there is a bias in the direction of better recall of one's own statements, individuals' estimates of the amount of time they themselves spoke should exceed the average speaking time attributed to them by the other member(s) of the group.

The results were consistent with this reasoning. For seven of the eight students in the undergraduate seminar, assessments of their own discussion time exceeded the average time estimate attributed to them by the other participants ($p < .05$, sign test). Similarly, in 10 of the 13 dyads, estimates of one's own discussion time exceeded that provided by the other participant ($p < .05$, sign test). The magnitude of the bias was highly significant over the 13 dyads, $F(1, 12) = 14.85$, $p < .005$; on the average, participants estimated that they spoke 59% of the time. These data provide preliminary, albeit indirect, evidence for the hypothesized availability bias in everyday situations.

The principle objectives of the current research were (a) to assess the ocurrence of egocentric biases in availability and attributions of responsibility in different settings; (b)

to examine factors that were hypothesized to influence these biases; and (c) to offer preliminary evidence of a relation between a bias in availability and a bias in attributions of responsibility. Experiment 1 assessed the occurrence of egocentric biases in availability and allocations of responsibility in a natural setting and examined the relation between the two biases. Next, a laboratory experiment was conducted to address the issue of whether the quality of the group's performance affects the availability bias: Is the tendency for one's own inputs to be more available reduced substantially when the group's performance is poor, as a *motivational* interpretation would suggest? Experiment 3 further examined the effects of success and failure in a natural setting. The experimental manipulations in Experiments 4 and 5 were designed to influence availability, and changes in attributions of responsibility were assessed. The manipulation in Experiment 4 induced *differential encoding;* the manipulation in Experiment 5 varied the *retrieval* cues provided to the subjects.

Experiment 1

In this experiment, we wished to examine egocentric biases in naturally occurring, continuing relationships. Married couples appeared to represent an ideal target group. Spouses engage in many joint endeavors of varying importance. This circumstance would appear to be rife with possibilities for egocentric biases.

Accordingly, the first experiment was conducted (a) to determine if egocentric biases in allocations of responsibility occur in marital relationships; (b) to replicate, using a different dependent measure, the egocentric bias in availability obtained in the pretest; and (c) to correlate the bias in availability with the bias in responsibility. If the bias in responsibility is caused by a bias in availability, the two sets of data should be related.

Method

Subjects

The subjects were 37 married couples living in student residences. Twenty of the couples had children. The subjects were recruited by two female research assistants who knocked on doors in the residences and briefly described the experiment. If the couple were willing to participate, an appointment was made. The study was conducted in the couple's apartment; each couple was paid $5 for participating.

Procedure

A questionnaire was developed on the basis of extensive preliminary interviews with six married couples. In the experiment proper, the questionnaire was completed individually by the husband and wife; their anonymity was assured. The first pages of the questionnaire required subjects to estimate the extent of their responsibility for each of 20 activities relevant to married couples by putting a slash through a 150-mm straight line, the endpoints of which were labeled "primarily wife" and "primarily husband."[1] The twenty activities were making breakfast, cleaning dishes, cleaning house, shopping for groceries, caring for your children, planning joint leisure activities, deciding how money should be spent, deciding where to live, choosing friends, making important decisions that affect the two of you, causing arguments that occur between the two of you, resolving conflicts that occur between the two of you, making the house messy, washing the clothes, keeping in touch with relatives, demonstrating affection for spouse, taking out the garbage, irritating spouse, waiting for spouse, deciding whether to have children.

Subjects were next asked to record briefly examples of the contributions they or their spouses made to each activity. Their written records were subsequently examined to assess if the person's own inputs were generally more "available." That is, did the examples reported by subjects tend to focus more on their own behaviors than on their spouses'? A rater, blind to the experimental hypothesis, recorded the number of discrete examples subjects provided of their own and of their spouses' contributions. A second rater coded one third of the data; the reliability (Pearson product-moment correlation) was .81.

Results

The responses of both spouses to each of the responsibility questions were summed,

[1] In the preliminary interviews, we used percentage estimates. We found that subjects were able to remember the percentages they recorded and that postquestionnaire comparisons of percentages provided a strong source of conflict between the spouses. The use of the 150-mm scales circumvented these difficulties; subjects were not inclined to convert their slashes into exact percentages that could then be disputed.

so that the total included the amount that the wife viewed as her contribution and the amount that the husband viewed as his contribution. Since the response scale was 150 mm long, there were 150 "units of responsibility" to be allocated. A sum of greater than 150 would indicate an egocentric bias in perceived contribution, in that at least one of the spouses was overestimating his or her responsibility for that activity. To assess the degree of over- or underestimation that spouses revealed for each activity, 150 was subtracted from each couple's total. A composite score was derived for the couple, averaging over the 20 activities (or 19, when the couple had no children).

An analysis of variance, using the couple as the unit of analysis, revealed that the composite scores were significantly greater than zero, $M = 4.67$, $F(1, 35) = 12.89$, $p < .001$, indicating an egocentric bias in perceived contributions. Twenty-seven of the 37 couples showed some degree of overestimation ($p < .025$, sign test). Moreover, on the average, overestimation occurred on 16 of the 20 items on the questionnaire, including negative items—for example, causing arguments that occur between the two of you, $F(1, 32) = 20.38$, $p < .001$. Although the magnitude of the overestimation was relatively small, on the average, note that subjects tended to use a restricted range of the scale. Most responses were slightly above or slightly below the halfway mark on the scale. None of the items showed a significant underestimation effect.

The second set of items on the questionnaire required subjects to record examples of their own and of their spouses' contributions to each activity. A mean difference score was obtained over the 20 activities (averaging over husband and wife), with the number of examples of spouses' contributions subtracted from the number of examples of own contributions. A test of the grand mean was highly significant, $F(1, 35) = 36.0$, $p < .001$; as expected, subjects provided more examples of their own ($M = 10.9$) than of their spouses' ($M = 8.1$) inputs. The correlation between this self–other difference score and the initial measure of perceived responsibility was determined. As hypothesized, the greater the tendency to recall self-relevant behaviors, the greater was the overestimation in perceived responsibility, $r(35) = .50$, $p < .01$.

The number of words contained in each behavioral example reported by the subjects was also assessed to provide a measure of elaboration or richness of recall. The mean number of words per example did not differ as a function of whether the behavior was reported to be emitted by self ($M = 10.0$) or spouse ($M = 10.1$), $F < 1$. Further, this measure was uncorrelated with the measure of perceived responsibility, $r(35) = -.15$, *ns*.

In summary, both the measure of responsibility and the measure reflecting the availability of relevant behaviors showed the hypothesized egocentric biases. Moreover, there was a significant correlation between the magnitude of the bias in availability and the magnitude of the bias in responsibility. This finding is consistent with the hypothesis that egocentric biases in attributions of responsibility are mediated by biases in availability. Finally, the amount of behavior recalled seemed to be the important factor, rather than the richness of the recall.

Experiment 2

The data from Experiment 1 indicate that egocentric biases in availability and attributions of responsibility occur in ongoing relationships. The remaining experiments were designed to demonstrate the prevalence of these phenomena, and to investigate some of the factors that were expected to influence their magnitude.

The major purpose of Experiment 2 was to evaluate the self-esteem interpretation of the availability bias. If the availability bias is caused primarily by the motivation to enhance self-esteem, recall of a joint endeavor should facilitate an acceptance of personal responsibility after success and a denial of personal responsibility after failure. Consequently, the self-esteem interpretation implies that self-generated inputs should be more available after success than after failure. The evidence from past research that

people accept more responsibility for a success than for a failure is consistent with this reasoning (e.g., Luginbuhl, Crowe, & Kahan, 1975; Sicoly & Ross, 1977; Wortman, Costanzo, & Witt, 1973).

In Experiment 2, subjects learned several days after participating in a problem-solving task that their group had performed either well or poorly. It was hypothesized that subjects would recall a greater proportion of their own statements when the group product was positively evaluated. Because we moved to the laboratory for this experiment, it was possible to tape record the group's initial interaction. This recording provided a "reality base" against which to compare the subsequent recall of subjects.

Method

Subjects

The subjects were 37 males and 7 females selected from lists of students living at the university. Subjects were paid $5 each. All of the subjects participated in both sessions.

Procedure

The experiment was conducted in two sessions separated by a 3- or 4-day interval. Subjects reported for the first session in groups of two. They were told that the purpose of the study was to determine whether groups exhibit more social awareness than individuals. They were given 10 minutes to read a case study of Paula, a psychologically troubled person (selected from Goldstein & Palmer, 1975). Each subject in the dyad was provided with different portions of the case study. The subjects were next asked questions designed to assess their psychological understanding of Paula's difficulties. They were told to discuss each question and arrive at a joint response, taking into account the different information that each group member brought with him or her to the case. Subjects were told that their discussions were being tape recorded. The experimenter informed them that she would listen to the tapes following the session to evaluate the group's answers.

Subjects returned individually for the second session. In a random one half of the dyads, subjects were led to believe that their group had performed poorly relative to other groups in the experiment (third from the worst). In the remaining dyads, subjects were informed that their group had performed relatively well (third from the best). Subjects were then told, "Write down as much as you can recall of your group's discussion of Paula. You will only have a short time to do this, so it is unlikely that you will be able to report all or even most of what was said. It is, therefore, important that you put things down in the order that they come to you. . . . If you remember the idea, but not the exact comment, rephrase it in your own words." Subjects were told not to record who said each statement. They were simply to write what was said.

Subjects were asked to stop writing at the end of 8 minutes and to go back over their responses to indicate who said each statement during the discussion. Finally, they were asked whether, in their opinion, each statement improved or lowered their group's score, or whether they were uncertain. Subjects were debriefed at the end of the second session.

An observer who was blind to the subjects' treatment conditions contrasted subjects' recall with their original comments on the tape to assess accuracy. A statement was judged to be accurate if it represented an idea that the subject expressed during the interaction, even though the actual words used during the discussion might have differed from the words recalled by the subject. A second rater scored a random one third of the tapes, and agreement was 93%.

Results and Discussion

Availability

The proportion of statements that subjects attributed to themselves was calculated for each member of the dyad. The average proportion for each dyad served as the unit of analysis. In 21 of the 22 dyads, the subjects attributed the majority of the statements that they recalled to themselves ($p < .001$, sign test). The average proportion of subjects' own statements was .70 in the success condition and .60 in the failure condition. Each of these proportions was significantly greater than a .50 or chance expectancy, $t(10) = 9.09$, $p < .001$, and $t(10) = 3.22$, $p < .01$, respectively. Thus, in both the success and failure conditions, subjects attributed significantly more of the recalled statements to themselves than would be expected by chance. Nevertheless, as hypothesized, subjects attributed a greater proportion of the recalled statements to themselves after a success than after a failure, $F(1, 20) = 7.10$, $p < .025$. The total number of statements recalled (adding over statements attributed to self and the other person) did not differ

significantly as a function of the group's performance ($F = 1.57$).

Accuracy

Subjects' recall was compared with the taped record in a 2 × 2 between–within analysis of variance (Success vs. Failure × Self vs. Partner), with the dyad as the unit of analysis. Subjects recalled a higher percentage of their own actual statements ($M = 5.6\%$) than of their partner's actual statements ($M = 2.6\%$), $F(1, 19) = 18.37$, $p < .001$.[2] Although the means seem low, note that subjects were given only an 8-minute recall period. The group's performance level did not affect the percentage of actual statements recalled (main effect and interaction Fs < 1).

We also compared the accuracy of the statements subjects attributed to themselves with the accuracy of the statements they attributed to their partners. Sixty-nine percent of the statements that subjects attributed to self were accurate reflections of self-generated comments; 56% of the statements that subjects attributed to their partners were accurate. The difference between these two percentages was significant, $F(1, 19) = 7.06$, $p < .025$. The group's performance level did not significantly affect the accuracy of the attributed statements (success–fail main effect $F = 1.14$, interaction $F < 1$).

Most of the errors that subjects made were of two types: They recalled material from the case history that had not been mentioned in the discussion; they reported inferences and conclusions that were not contained in the case history or in the discussion. In only a few instances (approximately 2% of the errors) did subjects take credit for statements made by their partners.

Evaluations

Finally, subjects' evaluations of the statements were transcribed onto a 3-point scale: +1 (improved the group's score), 0 (uncertain), and −1 (lowered the group's score). Two scores were obtained for each subject: the average rating of comments attributed to self and the average rating of statements attributed to the other person. An analysis of variance, with the dyad as the unit of analysis, revealed a main effect for success–fail, $F(1, 20) = 14.56$, $p < .005$, and a Success–Fail × Self–Other interaction, $F(1, 20) = 5.19$, $p < .05$.

The success–fail main effect indicated that statements were evaluated more positively following success ($M = .75$) than following failure ($M = .41$). The interaction revealed that whereas subjects' evaluations of their own comments were marginally lower in the failure condition than in the success condition (M difference $= .18$, $t = 1.85$, $p < .10$), their evaluations of the other person's comments were significantly lower in the failure condition than in the success condition (M difference $= .50$, $t = 5.14$, $p < .01$).

In summary, the present study provided some evidence for the self-esteem maintenance hypothesis. Subjects attributed a higher proportion of the recalled comments to themselves after success than after failure; subjects' evaluations of the recalled statements suggested an attempt to shift the blame for failure onto their partners. On the other hand, contrary to the self-esteem interpretation, recall was egocentric even in the failure condition.

Note that the strong egocentricity obtained on the recall measure and the increased accuracy of self-generated statements may reflect, in part, the fact that subjects initially read different aspects of the case history. Since they subsequently presented this material to the other person in responding to the questions, subjects' own contributions may have received more "study time." Nevertheless, this differential is ecologically valid. A person's inputs are often derived from his or her previous history and experiences.

Experiment 3

In Experiment 3 we examined the effects of success and failure in a more natural setting. We had the players on 12 intercollegiate basketball teams individually complete a

[2] The tapes from one of the failure groups were lost; this group is omitted from the analysis.

questionnaire in which they were asked to recall an important turning point in their last game and to assess why their team had won or lost.

It is a leap to go from the self–other comparisons that we have considered in the previous studies to own team – other team comparisons. There are, however, a number of reasons to expect that the actions of one's own team should be more available to the attributor than the actions of the other team: I know the names of my teammates, and therefore, I have a ready means of organizing the storage and retrieval of data relevant to them; our success in future games against other opponents depends more on our own offensive and defensive abilities than on the abilities of the opposing team. Consequently, I may attend more closely to the actions of my teammates, which would enhance encoding and storage. Also, there are informational disparities: The strategies of my own team are more salient than are the strategies of the opposing team (Tversky & Kahneman, 1973).

If the initiatives of one's own team are differentially available, players should recall a turning point in terms of the actions of their team and attribute responsibility for the game outcome to their team. On the basis of the data from Experiment 2, it may be expected that these tendencies will be stronger after a win than after a loss.

Method

Subjects

Seventy-four female and 84 male intercollegiate basketball players participated in the study. The team managers were contacted by telephone; all agreed, following discussions with their players, to have their teams participate in the study.

Procedure

The questionnaires were administered after six games in which the teams participating in the study played each other. Thus, for the three male games chosen, three of the six male teams in the study were competing against the other three male teams. Similarly, the three female games selected included all six of the female teams. The questionnaires were administered at the first team practice following the target game (1 or 2 days after the game), except in one case where, because of the teams' schedules of play, it was necessary to collect data immediately after the game (two female teams). The questionnaires were completed individually, and the respondents' anonymity was assured. The relevant questions, from the current perspective, were the following:

1. Please describe briefly one important turning point in the last game and indicate in which period it occurred.

2. Our team won/lost our last game because. . . .

The responses to the first question were examined to determine if the turning point was described as precipitated by one's own team, both teams, or the other team. Responses to the second question were examined to assess the number of reasons for the win or loss that related to the actions of either one's own or the opposing team. The data were coded by a person who was unaware of the experimental hypotheses. A second observer independently coded the responses from 50% of the subjects. There was 100% agreement for both questions.

Results

There were no significant sex differences on the two dependent measures; the results are, therefore, reported collapsed across gender. Since team members' responses cannot be viewed as independent, responses were averaged, and the team served as the unit of analysis.

A preliminary examination of the "turning point" data revealed that even within a team, the players were recalling quite different events. Nevertheless, 119 players recalled a turning point that they described as precipitated by the actions of their own team; 13 players recalled a turning point that they viewed as caused by both teams; 16 players recalled a turning point seen to be initiated by the actions of the opposing team (the remaining 10 players did not answer the question). Subjects described such events as a strong defense during the last 2 minutes of the game, a defensive steal, a shift in offensive strategies, and so on.

The percentage of players who recalled a turning point caused by their teammates was derived for each team. These 12 scores were submitted to an analysis that compared them to a chance expectancy of 50%. The obtained distribution was significantly different from chance, $F(1, 11) = 30.25$, $p < .001$, with a mean of 80.25%. As hypothesized,

most reports emphasized the actions of the players' own team.

The percentage of players who recalled a turning point caused by their teammates was examined in relation to the team's performance. The average percentage was higher on the losing team than on the winning team in five of the six games ($p < .11$, sign test). The mean difference between the percentages on losing ($M = 88.5$) and winning ($M = 72.$) teams was nonsignificant ($F < 1$).

The players' explanations for their team's win or loss were also examined. Of the 158 participants, only 14 provided any reasons that involved the actions of the opposing team. On the average, subjects reported 1.79 reasons for the win or loss that involved their own team and .09 reasons that involved the opposing team, $F(1, 11) = 272.91$, $p < .001$. Finally, the tendency to ascribe more reasons to one's own team was nonsignificantly greater after a loss ($M = 1.73$) than after a win ($M = 1.65$), $F < 1$.

Discussion

The responses to the turning point question indicate that the performances of subjects' teammates were more available than those of opposing team members. Further, subjects ascribed responsibility for the game outcome to the actions or inactions of their teammates rather than to those of members of the opposing team. Thus, biases in availability and judgments of responsibility can occur at the group level. Rather and Heskowitz (1977) provide another example of group egocentrism: "CBS (news) became a solid Number One after the Apollo moonshot in 1968. If you are a CBS person, you tend to say our coverage of the lunar landing tipped us over. If you are a NBC person, you tend to cite the break-up of the Huntley–Brinkley team as the key factor" (p. 307).

Contrary to the data from Experiment 2, the availability bias in Experiment 3 was as strong after failure as after success. There are differences between the studies that may contribute to this discrepancy. The "egocentric" availability and attributions in the basketball experiment were team rather than self-oriented; as a result, responsibility for failure was more diffused, and subjects' self-esteem was threatened less directly. Also, unlike the group in the laboratory study, the basketball team had a future: The players could enhance their control over subsequent game outcomes by locating causality within their own team. Finally, and perhaps most important, unlike the laboratory group, the team also had a past. Team members recalled aspects of their behavior that changed and attributed the game outcomes to these variations (e.g., we win because of discipline and hustle; we lose because of a lack of discipline and hustle). What players seemed to ignore, however, was that the opposing teams might contribute to these fluctuations.

It seems likely that a tendency to perceive both teams as responsible for the game outcome might increase with the magnitude of the win or loss (assuming that large wins or losses are atypical). As Kelley (1973) noted, multiple causes are necessary to explain extreme outcomes. Although no such tendency was observed in the current study, there were too few data points (games) to provide an accurate determination.

Experiment 4

In the final two experiments, we examined the hypothesized relation between the bias in availability and the bias in attributions of responsibility more directly by introducing manipulations that should affect availability and measuring changes in attribution. In Experiment 4, subjects were required to record either their own comments (self-focus condition) or those of the other person (partner-focus condition) during a problem-solving session. At a second session, subjects were shown their notes and asked to assess the extent to which either they or their partners had been responsible for various aspects of the decision-making process. It was assumed that the partner-focus condition would enhance encoding and retrieval of the partner's contributions. Thus, the partner's inputs would be more available when assessments of responsibility were made, and subjects should assign their partner more responsi-

bility for group decision-making in the partner-focus condition than in the self-focus condition.

Method

Subjects

The subjects were 40 males recruited from the introductory psychology subject pool.

Procedure

Subjects were scheduled in pairs for the first session. In a few introductory comments, the experimenter described the difficulty of preventing people from smoking. Subjects were then told they were participating in a pilot project to assess the efficacy of "brainstorming techniques" as a means of providing possible solutions to this problem. They were further informed that solutions generated during their discussion would be sent to the Committee for the Prevention of Cigarette Smoking (a government committee). Subjects were told to follow a four-step sequence: define the problem, generate as many solutions as possible, discuss the pros and cons of each proposed solution, and finally, select a preferred solution and explain the reasons for this choice.

Subjects in the self-focus condition were asked to keep a record of their own contributions to the discussion. Subjects in the partner-focus condition were asked to keep a record of only the other person's inputs: "This will leave you free to think and develop your ideas because your partner will be doing the writing." Subjects were given about 45 minutes for discussion.

Subjects returned individually for a second session 2–3 days later. Each subject was asked to look over the notes he had taken during the previous session, "in order to refresh your recollection of the discussion."

Subjects completed the dependent measures after they had reviewed their notes of Session 1. The principal dependent variable required subjects to indicate who tended to control the course and content of the discussion during the first session. They were asked to assess this overall, and also with respect to the various stages of the discussion, on 150-mm scales with endpoints labeled "the other person" and "me."

Results

A 2 × 2 analysis of variance was performed on the data. Self- versus partner focus was a between-subjects factor. Since the dyad was treated as an experimental unit, the response made by each member of the pair was considered to be a repeated measure.

The focus manipulation had no reliable impact on attributions of responsibility (all Fs < 1). Once again, however, there was strong evidence of an egocentric bias in allocations of responsibility. Subjects reported that they had exerted more control over the course and content of each segment of the discussion than their partners ascribed to them—solutions stage: 85 versus 68, $F(1, 18) = 7.32$, $p < .025$; evaluation stage: 79 versus 70, $F(1, 18) = 4.13$, $p < .07$; final proposal stage: 86 versus 67, $F(1, 18) = 11.31$, $p < .01$; overall discussion: 89 versus 72, $F(1, 18) = 9.21$, $p < .01$. Note that for each item, A's self-attributions were, on the average, beyond the midpoint of the 150-mm scale, indicating a perceived contribution of greater than 50%; on the other hand, the partner viewed A's contributions as being less than 50% in each instance.

Discussion

The results revealed strong egocentric biases in individuals' attributions of responsibility for segments of the problem-solving task. The focus manipulation had surprisingly little effect, however. What we had viewed to be a sledgehammer manipulation turned out to be ineffective.

Why did the attention manipulation have so little impact? One possibility is that subjects may have found the written records to be relatively uninformative and relied more on their memories than on the notes in responding to the questionnaire (hence, the strong egocentric biases). The notes may have appeared inadequate, in part because they were very brief, usually about one page, relative to the length of the interaction (45 minutes). Moreover, much of what subjects wrote may have seemed irrelevant to the final decisions made by the group. In short, we may not have succeeded in focusing subjects' attention on what, from their perspective, were the important aspects of the interaction. To obtain this information they were, perhaps, only too willing to rely on their memories.

Finally, note that recent research on the relation between attention and recall in interpersonal perception settings has yielded

inconsistent results (Taylor & Fiske, 1978). This situation stands in marked contrast to the strong relation evident in the cognitive literature (Cofer, 1977; Loftus & Loftus, 1976). Unlike the constrained experimental settings utilized in cognitive research, however, the present study and those reviewed by Taylor and Fiske incorporate rich social environments. Consequently, the manipulation of attention is relatively gross; it is less certain that the individual is attending to those aspects of the situation that are relevant to the dependent measures.

Experiment 5

In Experiment 5, we again attempted to vary the individual's focus of attention so as to affect availability. In this experiment, however, we employed a manipulation designed to promote selective retrieval of information directly relevant to attributions of responsibility.

In our initial analysis, we suggested that egocentric attributions of responsibility could be produced by the selective retrieval of information from memory and that retrieval might be guided by the kinds of questions that individuals ask themselves. Experiment 5 was conducted to test this hypothesis. Subjects were induced to engage in differing retrieval by variations in the form in which questions were posed. Graduate students were stimulated to think about either their own contributions to their BA theses or the contributions of their supervisors. The amount of responsibility for the thesis that subjects allocated to either self or supervisor was then assessed. It was hypothesized that subjects would accept less responsibility for the research effort in the supervisor-focus than in the self-focus condition.

Method

Subjects

The subjects were 17 female and 12 male psychology graduate students. Most had completed either 1 or 2 years of graduate school. All of these students had conducted experiments that served as their BA theses in their final undergraduate year.

Procedure

The subjects were approached individually in their offices and asked to complete a brief questionnaire on supervisor–student relations. None refused to participate. The two forms of the questionnaire were randomly distributed to the subjects; they were assured that their responses would be anonymous and confidential.

One form of the questionnaire asked the subjects to indicate their own contribution to each of a number of activities related to their BA theses. The questions were as follows: (a) "I suggested _____ percent of the methodology that was finally employed in the study." (b) "I provided _____ percent of the interpretation of results." (c) "I initiated _____ percent of the thesis-relevant discussions with my supervisor." (d) "During thesis-related discussions I tended to control the course and content of the discussion _____ percent of the time. (e) "All things considered, I was responsible for _____ percent of the entire research effort." (f) "How would you evaluate your thesis relative to others done in the department?"

The second form of the questionnaire was identical to the above, except that the word *I* (self-focus condition) was replaced with *my supervisor* (supervisor-focus condition) on Questions 1–5. Subjects were asked to fill in the blanks in response to the first five questions and to put a slash through a 150-mm line, with endpoints labeled "inferior" and "superior," in response to Question 6.

Results and Discussion

For purposes of the analyses, it was assumed that the supervisor's and the student's contribution to each item would add up to 100%. Though the experiment was introduced as a study of supervisor–student relations, it is possible that the students may have considered in their estimates the inputs of other individuals (e.g., fellow students). Nevertheless, the current procedure provides a conservative test of the experimental hypothesis. For example, if a subject responded 20% to an item in the "I" version of the questionnaire, it was assumed that his or her supervisor contributed 80%. Yet the supervisor may have contributed only 60%, with an unspecified person providing the remainder. By possibly overestimating the supervisor's contribution, however, we are biasing the data against the experimental hypothesis: The "I" version was expected to reduce the percentage of responsibility allocated to the supervisor.

Subjects' responses to the first five questions on the "I" form of the questionnaire were subtracted from 100, so that higher numbers would reflect greater contributions by the supervisor in both conditions. Question 5 dealt with overall responsibility for the research effort. As anticipated, subjects allocated more responsibility to the supervisor in the supervisor-focus ($M = 33.3\%$) than in the self-focus ($M = 16.5\%$) condition, $F(1, 27) = 9.05$, $p < .01$. The first four questions were concerned with different aspects of the thesis, and the average response revealed a similar result: supervisor-focus $M = 33.34$; self-focus $M = 21.82$; $F(1, 27) = 5.34$, $p < .05$. Finally, subjects tended to evaluate their thesis more positively in the self-focus condition than in the supervisor-focus condition: 112.6 versus 94.6, $F(1, 27) = 3.59$, $p < .10$.

The contrasting wording of the questions had the anticipated impact on subjects' allocations of responsibility. The supervisor version of the questionnaire presumably caused subjects to recall a greater proportion of their supervisors' contributions than did the "I" form of the questionnaire. This differential availability was then reflected in the allocations of responsibility. Note, however, that the questions were not entirely successful in controlling subjects' retrieval. The supervisor was allocated only one third of the responsibility for the thesis in the supervisor-focus condition.

In light of the present data, the basketball players' attributions of responsibility for the game outcome in Experiment 3 need to be reexamined. Recall that the players were asked to complete the sentence, "Our team won/lost our last game because. . . ." This question yielded a highly significant egocentric bias. With hindsight, it is evident that the form of the question—"*Our* team . . . *our* last game"—may have prompted subjects to focus on the actions of their own teams, even though the wording does not preclude references to the opposing team. The "turning point" question in Experiment 3 was more neutrally worded and is not susceptible to this alternative interpretation.

The leading questions in these studies emanate from an external source; many of our retrieval queries are self-initiated, however, and our recall may well be biased by the form in which we pose retrieval questions to ourselves. For example, basketball players are probably more likely to think in terms of "Why did *we* win or lose?" than in terms of a neutrally phrased "Which team was responsible for the game outcome?"

General Discussion

The five studies employed different subject populations, tasks, and dependent measures. As hypothesized, the egocentric biases in availability and attribution appear to be robust and pervasive.

Determinants of the Availability Bias

Several processes were hypothesized to contribute to the increased availability of self-generated inputs. It is possible to consider how well each accounts for the existing data. *Selective encoding* and *storage* cannot have contributed to the effects of success versus failure on availability in Experiment 2 or of supervisor- versus self-focus in Experiment 5 (since these manipulations occurred long after encoding and storage took place). *Informational disparities* should not have contributed to the pretest results (subjects' time estimates were based solely on the preceding discussion), to the tendency to attribute a higher proportion of the recalled statements to oneself in the success as compared to the failure condition in Experiment 2, or to the effects of supervisor- versus self-focus in Experiment 5 (since neither performance level, as operationalized here, nor focus could affect the information initially available to the subjects). Two *motivational processes* were posited. Self-esteem maintenance does not seem pertinent to the results obtained from the two-person groups in the pretest. Nor does it account for (a) the overrecall of self-generated inputs in the failure condition of Experiment 2 and (b) the finding that players on losing basketball teams recalled the turning point of the game in terms of the actions of their teammates. The control motivation hypothesis fares somewhat better. Although focusing on one's own inputs in failure situations may lower self-esteem, it

does permit one to perceive personal control over the activity. Hence, efficacy motivation could account for these results. Nevertheless, a desire for personal efficacy does not appear to explain all of the data. The two-person groups in the pretest seem to reveal a relatively "pure" information-processing effect: It is unlikely that people would feel a need to report that they dominated casual conversations. Also, the effect of supervisor- versus self-focus in Experiment 5 appears to be mediated by differential retrieval. Efficacy considerations may have induced the subjects to report that they were major contributors to their theses; nonetheless, motivational concerns do not dictate that focusing on the supervisor's contributions will reduce one's need to assume responsibility.

In summary, selective encoding and storage, informational disparities, and motivational influences do not appear to be necessary determinants of the egocentric bias in availability. The one remaining process that was posited, *selective retrieval*, is not precluded by any of the current data; further, it receives direct support from the findings in Experiments 2 and 5.

Nevertheless, it seems premature to eliminate any of the hypothesized processes as sufficient causes of the availability bias. The tendency of spouses to recall their own contributions in Experiment 1 may reflect informational disparities; the desire to maintain self-esteem may have contributed to the effect of performance level in Experiment 2; basketball players' responses to the turning point question in Experiment 3 may well have been influenced by selective encoding and by control motivation.

We suspect that, like many cognitive phenomena (cf. Erdelyi, 1974; Erdelyi & Goldberg, in press; McGuire, 1973), biases in availability are multidetermined in real life. Multidetermination may seem an unsatisfying resolution; however, it is one that social psychologists shall probably confront increasingly as they begin to study cognitive phenomena in situ. Researchers in other sciences face parallel complexities. For example, similar cancers appear to have different etiologies, depending, among other factors, on the environment in which the patient lives (Goodfield, 1976).

The Link Between Availability and Attributions of Responsibility

The focus of the present research has been on demonstrating that the hypothesized biases in availability and attribution exist and are relatively ubiquitous. It was also hypothesized, however, that the egocentric bias in attributions of responsibility would be mediated by the bias in availability. Although the data are suggestive, we have no definitive evidence that the bias in availability *causes* the bias in responsibility. The strongest affirmative evidence is that the two biases were significantly correlated in the marriage study and that a manipulation designed to induce selective retrieval influenced attributions of responsibility (Experiment 5). In opposition, it might be contended that the covariation between the two biases is susceptible to a number of alternative causal interpretations and that there is no direct evidence that the retrieval manipulation in Experiment 5 affected availability. Conceivably, the attributions of responsibility in Experiment 5 were mediated by some other factor not yet identified. Further evidence will be required to establish whether the bias in responsibility is caused by the bias in availability. The present results suggest several additional considerations, however, concerning the determinants and pervasiveness of the biases.

Pervasiveness of the Egocentric Biases

The egocentric biases obtained in the current studies may seem inconsistent with Jones and Nisbett's (1971) proposal that actors locate causality for their actions primarily within their environment. There are a number of differences between the two paradigms that might account for the discrepancy. Most important, Jones and Nisbett were concerned with interpretation, whereas we focused on recall and judgments of responsibility. Actors could presumably overestimate their contributions to a joint product and, at the same time, locate the cause of their behavior with-

in the environment. For example, suppose that a wife who reports that she does 80% of the cleaning is asked *why* she cleans (the central question for Jones and Nisbett). She may respond that the house is dirty, an environmental attribution. Conversely, her husband, who perhaps accepts 30% of the responsibility for cleaning, may answer the same question by pointing out that his wife has a fetish for cleanliness, a trait attribution.

Thus, the current data do not speak directly to the Jones and Nisbett hypothesis. Nevertheless, our data do seem to contradict related evidence that the responses of actors are more salient and available to observers than to actors themselves (Storms, 1973; Taylor & Fiske, 1975). The critical variable may be the extent to which the observer departs from a passive role and interacts with the actor. When, as in the present research, individuals undertake complex social interactions, they alternate between the roles of speaker (actor) and listener (observer), yet much of their attention may be directed at planning and executing their own responses. Although they do not attend to themselves perceptually, they may be cognitively self-focused; therefore, self-generated inputs are likely to be more available in recall. On the other hand, passive observers may concentrate on other persons in their environment. Also, observers may be less self-absorbed when their own responses require little attention, as, for example, when they enact well-practiced behaviors (Langer, 1978, has speculated that a wide range of social behaviors require minimal thought).

These instances notwithstanding, the present research demonstrates the prevalence of self-centered biases in availability and judgments of responsibility. In everyday life, these egocentric tendencies may be overlooked when joint endeavors do not require explicit allocations of responsibility. If allocations are stated distinctly, however, there is a potential for dissension, and individuals are unlikely to realize that their differences in judgment could arise from honest evaluations of information that is differentially available.

Ambient Temperature and the Occurrence of Collective Violence: A New Analysis

J. Merrill Carlsmith and Craig A. Anderson
Stanford University

Prevalent folklore suggests that riots tend to occur during periods of very hot weather. Baron and Ransberger examined 102 major riots in the United States between 1967 and 1971 and concluded that the frequency of collective violence and ambient temperature are curvilinearly related. The present article points out that the Baron and Ransberger analysis did not take account of the different number of days in different temperature ranges. The artifact is eliminated, and the probability of a riot, conditional upon temperature, is estimated. When this is done, the evidence strongly suggests that the conditional probability of a riot increases monotonically with temperature. Some general implications of such data analyses are discussed.

In a recent article in this journal, Baron and Ransberger (1978) presented an analysis of the relationship between the frequency of major riots and the ambient temperature occurring during the riots. To do this, they studied 102 major riots in the United States between 1967 and 1971. The hypothesis they wished to test, and for which they claimed confirmatory evidence, is the existence of a curvilinear relationship between the likelihood of a riot and the maximum ambient temperature at the time of the riot. This hypothesis contrasts with the prevalent folklore that riots tend to occur during periods of very hot weather. Specifically, Baron and Ransberger concluded that the likelihood of a riot increases with temperature up to the range of 81°–85° F and then decreases sharply with further increases in temperature. The evidence that they presented to support this relationship is a frequency distribution of the number of riots plotted against temperature. This frequency polygon does indeed peak in the interval 81°–85° F, falling off sharply on either side.

We contend that this relationship is an artifact of the particular way the data were examined and that an appropriate reanalysis suggests a monotonically increasing function relating the probability of riots and temperature. Basically, we argue that the Baron and Ransberger results stem from their having not taken account of base-rate differences in temperature. For example, if days in the 81°–85° F range are more common than days in the 91°–95° F range, there may well be more riots in the former range. There are, after all, many more opportunities for riots. But an appropriate analysis may well show that riots are *relatively* more common in the higher temperature range. To be sure, Baron and Ransberger did consider this possibility, but they rejected it. In our view, their rejection was premature; we consider their arguments and the weaknesses therein at greater length below.

The activities reported herein were supported in part by funds from Boys Town. However, the opinions expressed or the policies advocated do not necessarily reflect those of Boys Town. The research was carried out while the first author was a member of the Boys Town Center for the Study of Youth Development at Stanford University and while the second author was supported by a National Science Foundation Fellowship. We are indebted to Bradley Efron, Lee Ross, and Amos Tversky for their comments and suggestions on this work, and to Joy Davis for her assistance in the seemingly unending task of transcribing 58,000 temperatures.

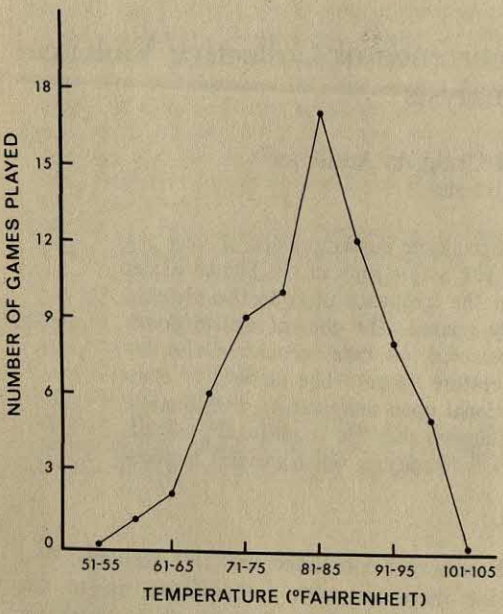

Figure 1. Frequency of baseball games played (New York Mets, 1977) as a function of ambient temperature.

Baseball, Temperature, and Base Rates

To see most clearly how this artifact may work, it is instructive to apply the same analysis used by Baron and Ransberger to a set of events that we know are not influenced by temperature. Figure 1 shows the same analysis used by Baron and Ransberger applied to the frequency of New York Mets baseball games played at home in 1977 (*The Sporting News*, April–October 1977). That is, we plot the frequency of Mets home games against the maximum ambient temperature in New York on the day of the game. (To be sure, baseball games occur primarily during the summer months, but then again, so do riots.) A brief study of Figure 1 shows a remarkable similarity to Figure 1 in the Baron and Ransberger (1978) article, and were we to follow their logic, we would have to conclude that "inspection of this figure lends support to the suggestion of a curvilinear relationship between ambient temperature and the incidence of [baseball games]" (p. 354). In view of the fact that baseball games are scheduled some months in advance, such a conclusion hardly seems warranted. Another explanation seems far more plausible. Both frequency polygons lead to erroneous conclusions, and for the same reason—the base-rate of different temperatures has not been taken into account. In our baseball example, it is not difficult to see that the frequency distribution of Mets home games is heavily influenced by the base-rate of daily maximum temperatures in New York during this period. Fewer games were played at temperatures of 91°–95° F, not because such temperatures lowered the probability of players choosing to play baseball, but because there were fewer such days. This simple example captures the essence of our critique of the Baron and Ransberger analysis, although the problem becomes a good deal more complex when we try to deal with the data they present.

The failure to consider base rates when assessing the probability of some event is hardly unique to this example. It is a problem of general concern in the analysis of data when we wish to calculate the probability of an event, conditional on the occurrence of some other event. It is also a problem that has begun to intrigue cognitive psychologists interested in subjective assessments of probability rather than formal statistical estimation. For example, in the context of a discussion of judgmental heuristics, Tversky and Kahneman (1974) comment:

> The reliance on heuristics and the prevalence of biases are not restricted to laymen. Experienced researchers are also prone to the same biases—when they think intuitively. For example, the tendency to predict the outcome that best represents the data, with insufficient regard for prior probability, has been observed in the intuitive judgments of individuals who have had extensive training in statistics. Although the statistically sophisticated avoid elementary errors, such as the gambler's fallacy, their intuitive judgments are liable to similar fallacies in more intricate and less transparent problems. (p. 1130)

Temperatures Before and After Riots (and Baseball Games)

The second major group of data presented by Baron and Ransberger is a plot of the maximum daily temperatures in the riot city during the 7 days prior to the occurrence of each riot and the 3 days following the riot. This plot shows gradually increasing tempera-

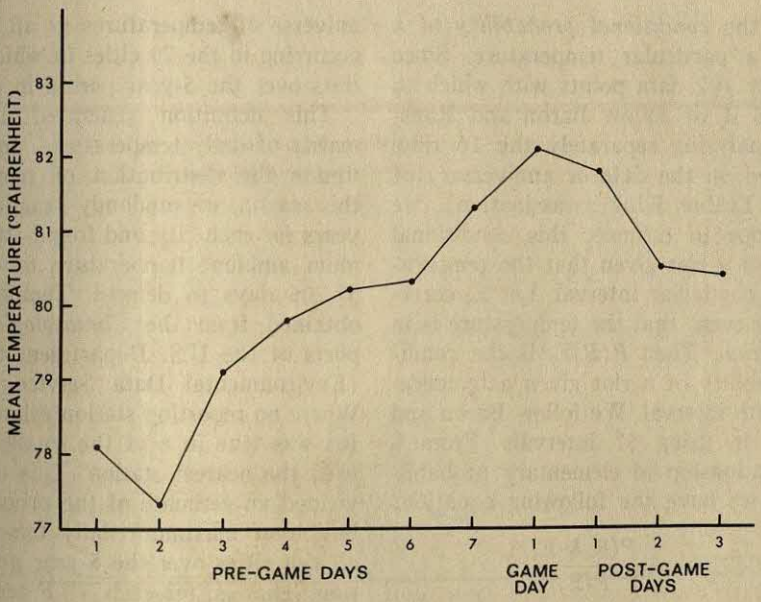

Figure 2. Mean maximum ambient temperature on the 7 days preceding the baseball game, on the game day, and on the 3 days following the game day.

tures up to the day of the riot, followed by decreasing temperatures during the 3 days following the riot. It should be noted that although this picture is consistent with their curvilinear hypothesis, it is also consistent with a wide variety of other possible functional relationships between temperature and the probability of riots. In particular, it is perfectly consistent with our hypothesis that there is a monotonically increasing relationship between temperature and the probability of a riot. On the other hand, the plot is equally consistent with a hypothesis that states that on occasional rainy (and cooler) days, riots (or baseball games) are unlikely to occur. Thus, the same picture could occur regardless of the true relationship between likelihood of a riot and temperature at the outbreak of a riot. Figure 2 shows a plot, again parallel to Baron and Ransberger's Figure 2, but done for New York Mets home games in 1977. Again we see a remarkable similarity between Baron and Ransberger's Figure 2 for riots and our Figure 2 for baseball games. It is our tentative hypothesis that our Figure 2 is mediated by a few rainy days, on which temperatures tend to be cooler and baseball games tend not to be played, but we are less certain of this artifact than we are of the artifact underlying Figure 1. In view of the fact that Baron and Ransberger's Figure 2 is consistent with a wide variety of possible functional relationships between temperature and the probability of riots, we will not pursue this issue further but return to the more fundamental question. If the postulated curvilinear relationship between temperature and the probability of riots is artifactual, what is the nature of the true relationship?

Conditional and Unconditional Probabilities

It is easier to point to the dangerous artifact underlying Figure 1 than to see a perfect solution to it. We present two alternative analyses below. Neither is immune to criticism, although both remove the obvious artifact. The consistency that emerges from these two very different analyses leads us to some confidence in the conclusions they imply, although we would emphasize at the outset our qualms about drawing any firm conclusions from this type of correlational analysis.

To see how to remove the effect of base rates, it is instructive to formalize our discussion slightly. The quantity we wish to

estimate is the *conditional probability* of a riot, given a particular temperature. Since we have only 102 data points with which to work (or 86 if we follow Baron and Ransberger in analyzing separately the 16 riots that occurred on the date or anniversary of the Martin Luther King assassination), we can only hope to estimate this conditional probability of a riot given that the temperature is in a particular interval. Let E_i correspond to the event that the temperature is in the ith interval. Then $P\{R|E_i\}$is the conditional probability of a riot given a temperature in the ith interval. We follow Baron and Ransberger in using 5° intervals. From a familiar relationship in elementary probability theory, we have the following equation:

$$P(R|E_i) = \frac{P(R \ \& \ E_i)}{P(E_i)}.$$

That is, the conditional probability of a riot, given that the temperature is in a particular interval, is given by the joint probability of a riot and a temperature in a particular interval, divided by the probability that the temperature is in that interval.[1] Examination of the equation makes it clear that Baron and Ransberger essentially estimated the joint probability without correcting for the marginal temperature distribution.

Our problem, then, is to estimate that marginal distribution. It is not such an easy problem as it might appear, since the universe from which the particular riot temperatures are to be viewed as a sample is not well defined. We might attempt to conceptualize it as the distribution of all temperatures in the United States in the 5-year period in question. But a moment's thought shows the vagueness of that conceptualization. Should that distribution be weighted by the population density in each geographical location? Does it include the temperatures at Death Valley, where there are too few people to stage a convincing riot? Alternatively, we might try the distribution of temperatures in cities larger than, say, 100,000 people, again over the 5-year period in question. But some riots occurred in much smaller cities. Furthermore, no riots occurred in Alaska. Should we then include Alaska in our universe? Our solution to this problem was to define the universe of temperatures as all temperatures occurring in the 79 cities in which there were riots over the 5-year period in question.[2]

This definition generated a 79 × 1,826 matrix of daily temperatures. In order to estimate the distribution of temperatures in this matrix, we randomly sampled 2 of the 5 years for each city and found the daily maximum ambient temperature for each of the 57,705 days so defined. Temperatures were obtained from the *Climatological Data* reports of the U.S. Department of Commerce (Environmental Data Service, 1967–1971). Where no reporting station existed in the city (as was true in 6 of the smaller towns), we used the nearest station. This method, then, yielded an estimate of the probability distribution of maximum daily temperature over all riot cities over the 5-year period in question. That is, for each 5° F temperature interval, we had a count of the number of days in which the maximum temperature was in that interval. Dividing that count by 57,705 (the total number of days sampled) yielded an estimate of the probability of a day in

---

[1] An urn model may serve to clarify this point. Suppose we imagine an urn with a large number of marbles, each marked with a temperature. Most of the marbles are white, but a few are blue. The blue marble corresponds to a riot. To estimate the marginal distribution of temperature, we draw a sample of marbles and plot the temperatures. To estimate the probability of a riot, we draw a sample of marbles and count the number of blue marbles. To estimate the joint probability of riots and temperature, we draw a sample of marbles and count the number of blue ones in each temperature range. To estimate the conditional probability of a riot given a particular temperature, we draw a large sample, count the number of blue marbles in a particular temperature range, and divide that count by the total number of marbles in that temperature range. This final number is interpreted as follows: If we are told that we have a marble in a particular temperature range, the conditional probability tells us the number of chances that it is blue. So we wish to know for our data, Given that the temperature is between 81° and 85° F, what is the conditional probability of a riot? Having estimated this conditional probability for each interval, we then ask how these conditional probabilities vary with temperature.

[2] We are indebted to Robert A. Baron for providing us with the list of cities and dates of the 102 riots used in their study.

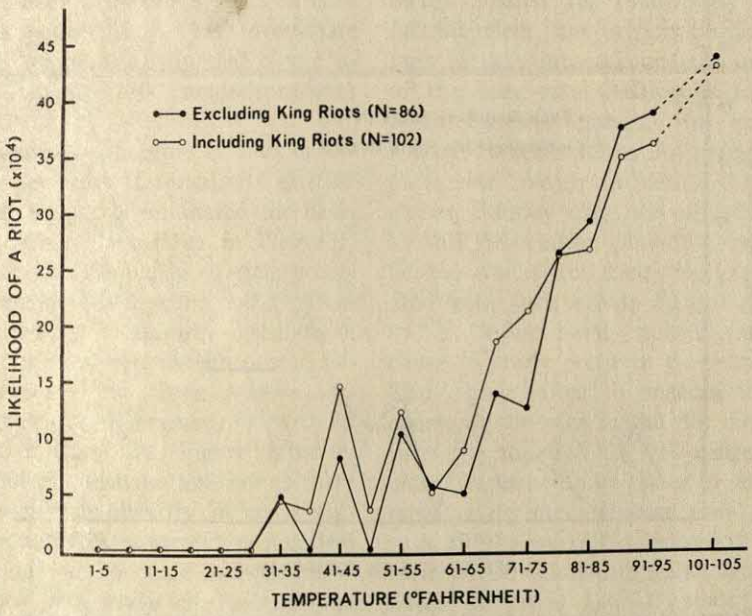

Figure 3. Conditional probability (likelihood) of a riot as a function of ambient temperature.

which the maximum temperature was in that interval. To estimate the conditional probability of a riot, given that the temperature was in a particular interval, we calculated the number of occurrences of a riot with a temperature in that range and divided by the number of days with a temperature in that range. The resulting function is shown in Figure 3.[3]

It is apparent that Figure 3 provides no evidence for a curvilinear relationship. Instead, there is a continuously increasing likelihood of riots as the temperature continues to rise, at least up through the temperature range of 91°–95° F. Contrary to the assertion of Baron and Ransberger, riots do not seem to be most likely at temperatures between 81° and 85° F; rather they become more and more likely with increasing temperature. This different function, of course, is a consequence of the fact that although there are fewer riots on days when the temperature is, say, 91°–95° F than on days when the temperature is 81°–85° F, there are many fewer days in the higher temperature range. The smaller number of riots at extremely high temperatures appears to be the result of many fewer opportunities for riots to occur; the conditional probability of a riot is larger at the higher temperature.

Three brief methodological notes are in order about Figure 3. First, there is a total of only three riots in the highest three temperature intervals, making the probability estimates extremely unstable. Consequently, we have averaged the three points, and this average is connected to the remainder of the function by a dashed line. Second, in defining the maximum daily temperature associated with each riot, we used the temperature on the day the riot began. This method contrasts with that of Baron and Ransberger, who took the average of the daily temperatures over the duration of the riot, for those riots that lasted more than 1 day. It seemed to us that if one wants to consider temperature as a causative factor in the outbreak of riots, it is more sensible to measure the temperature at the time of the outbreak rather than to include temperatures over subsequent days. Clearly, the temperature on

[3] We have followed Baron and Ransberger in estimating each function twice—once including the Martin Luther King-related riots and once excluding them.

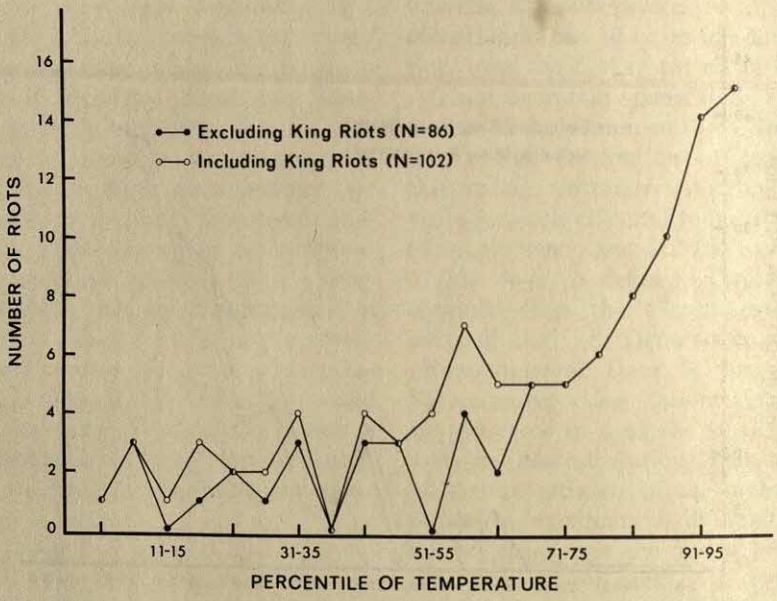

Figure 4. Frequency of collective violence (riots) as a function of the relative ambient temperature (expressed in percentiles).

July 12 cannot be more influential in determining whether a riot begins on July 10 than is the temperature on July 10. If we were to follow the Baron and Ransberger definition, there would be some minor changes in our Figure 3. Since we know that temperatures following the onset of a riot tend to be less extreme than temperatures on the first day of the riot, it is not surprising to find that extreme temperatures are slightly less common if we average over the days of the riot and that the proportion of riots at the modal temperature increases slightly. Even were we to use this averaging, the function still fails to show the precipitous drop that made Figure 1 so compelling, and the riot probability still reaches its maximum in the highest temperature range. Third, we present no inferential statistics in conjunction with this figure. It is our view that such statistics are, at best, irrelevant to these data and, at worst, seriously misleading. In their analysis of Figure 1, Baron and Ransberger present chi-square statistics. As we have already seen, such a calculation rests on an assumption that all temperature intervals are equally likely—an assumption that is demonstrably false. Furthermore, the riots show strong temporal and geographical dependencies (for example, five riots occurred in different cities in Michigan in a 3-day interval), which make assumptions of independence untenable.

An Alternative Analysis

Although Figure 3 casts severe doubts on the curvilinearity hypothesis, it is not totally convincing by itself. We have already alluded to the somewhat arbitrary definition of the universe of temperature days. Furthermore, the base-rate information used in the calculation of Figure 3 can be overly influenced by an extreme temperature distribution in one or two cities (although the large number of data points makes this somewhat implausible). Still, we are adding across rather dissimilar temperature distributions. A quite different analysis, which avoids these particular difficulties, involves looking at each riot temperature relative to all temperatures in the riot city. Thus, we estimate the cumulative distribution function (cdf) for all temperatures in City K and then look at the temperature on the day of the riot in that city relative to the cdf of all temperatures in that city. This procedure converts each riot temperature to a percentile relative to all temperatures in the riot city. Again, we use the

random sample of 2 of the 5 years in each city over the period 1967–1971 to estimate the cdf of all temperatures in that city, estimating each cdf by 730 (nonindependent) points.

Figure 4 shows the number of riots occurring at each percentile interval. By shifting to percentiles, we have eliminated the base-rate problem that plagued us in Figure 1. When we plot the frequency of riots occurring at different percentiles, the null hypothesis clearly predicts a uniform distribution. Any effect of the different likelihoods of different temperatures has been removed by expressing each riot temperature relative to all temperatures in that city. Figure 4 hardly suggests a uniform distribution, nor is there any evidence of curvilinearity. What is suggested is a monotonically increasing function. Thus, once again we conclude that the likelihood of a riot in a given city increases as the maximum ambient daily temperature in that city increases.

It should be noted that Figure 4 examines the covariation of riots and the relative temperature (relative to all temperatures in that particular city) rather than the riots' covariation with the absolute temperature. The relationship between relative and absolute temperature is strong enough (although by no means perfect) that we see no hope of using these data to answer the fascinating question of whether absolute temperature or relative temperature (relative to some adaptation level) is more important in predicting the likelihood of a riot. Rather, we see the convergence of these two functions, based on very different methods of analysis, as lending support to the general proposition that, at least for these particular riots, the probability of a riot increases monotonically with increasing maximum ambient temperatures in potential riot cities.

Attempts to Discount the Base-Rate Artifact

In view of the dramatic differences in conclusions that we draw after taking account of different temperature base rates, it is worth considering why Baron and Ransberger rejected this artifact as an explanation of their results and why we feel that the rejection was in error. They present several arguments against the plausibility of the artifactual effect, but each is particularistic and fails to take into account the overall impact of the base rate. Analogous to our use of Mets baseball games, for example, they looked at celebrations following victories in particular major athletic contests (bowl games, Stanley Cup play-offs, National Basketball Association play-offs, and the World Series) and found that temperatures associated with such events do not peak at 81°–85° F. Unfortunately, none of the events they chose to study occur in the summer months. Thus, they failed to observe that over the course of the year in the riot cities, temperatures in the 81°–85° F range are indeed more frequent than those in any other interval. The only evidence they present relevant to the overall distribution comes from their second counterargument against it. They select 11 cities and 2 months (July and August) and show that temperatures in the 81°–85° F range are not uniformly most frequent in those cities in those months. But different choices of cities, months, and temperature intervals lead to different conclusions, none of which describe the overall temperature distribution. As we have shown above, temperatures in the 81°–85° F range are in fact the most common temperatures in these cities. Baron and Ransberger's other arguments have this same particularistic quality, focusing primarily on temperatures in particular ranges in riot cities on the same dates in riot years versus nonriot years, and we do not consider them in detail here.

A Final Note

We close with a final set of cautionary remarks. We feel quite confident that these data do not provide support for the hypothesis of a curvilinear relationship between temperature and the probability of a riot. We feel reasonably confident that for these particular riots, there is good evidence for a monotonically increasing relationship between temperature and the probability of a riot.[4] However, facile generalizations from

[4] These remarks about the monotonic character of the relationship between temperature and the likeli-

these data make us very nervous. The riots are certainly not independent of one another; the dependencies cannot easily be described. The temperatures are not independent; again the dependencies are complex. Thus, from the point of view of inferential statistics, the number of true independent data points is unknown and may be small. Not only are the data fraught with all of the ambiguities of any correlational study, the data analyses are also subject to subtle, difficult, and complex effects. Even if the present data analysis seems satisfactory, there are numerous alternative explanations of the relationship. A clear understanding of the psychological effects of temperature, and particularly the effects of temperature on aggression, seems much more likely to emerge from experimental work like that of Baron (1972), Baron and Bell (1976), or Baron and Lawton (1972).

hood of riots are restricted to the normal range of temperatures. Clearly, at some point the relationship must become curvilinear. We seriously doubt that riots are likely to occur when the temperature is 120° F (although we have no data one way or the other).

Affective Space is Bipolar

James A. Russell
University of British Columbia, Vancouver, Canada

Numerous previous studies found monopolar rather than bipolar dimensions of affect (defined as emotion represented in language), but may have included methodological biases against bipolarity. The present study of self-report data ($N = 150$) on 11 affect scales showed that response format and acquiescence response style significantly shifted correlations between hypothesized opposites away from showing bipolarity. When these biases were taken into account, pleasure was found to be the bipolar opposite of displeasure and arousal of sleepiness. In turn, pleasure–displeasure and degree of arousal formed a two-dimensional bipolar space that accounted for almost all of the reliable variance in Thayer's four factors of activation plus a measure of depression. Dominance and submissiveness factors were also included in the study, but invalidity of the scales used precluded any conclusions regarding their bipolarity.

Early work on affect (emotion as represented in language) was based on the assumption that its descriptive dimensions would be bipolar: "An affective scale is a bipolar one" (Guilford, 1954, p. 264). Nowlis (e.g., Nowlis & Nowlis, 1956) similarly began his factor-analytic work on affect by hypothesizing four bipolar dimensions: pleasantness–unpleasantness, activation–deactivation, positive–negative social orientation, and control–lack of control. He gathered adjectives to measure each dimension and, in a series of studies, factor-analyzed the intercorrelations among responses to those adjectives. "How [did] these results relate to our original hypotheses? First, we had assumed that each factor would be bipolar. Actually, bipolarity was almost nonexistent in the obtained axes" (Nowlis, 1965, p. 358). His hypothesized opposites had tended to form two separate, independent monopolar factors instead of single bipolar ones.

Borgatta (1961), Clyde (1963), and McNair and Lorr (1964) subsequently reported the results of additional factor-analytic studies on affect in which monopolar, as opposed to bipolar, factors were consistently obtained. Thayer (1967) investigated what had originally been hypothesized to be a single, bipolar affective dimension, degree of activation or arousal, and obtained four independent monopolar factors, which he termed *general activation, high activation, deactivation-sleep,* and *general deactivation.* Indeed, most investigators of affect now argue against the existence of bipolar affective dimensions (e.g., Bradburn, 1969; Hall, 1977; Izard, 1972; McLachlan, 1976; Westbrook, 1976).

In other words, considerable research has tended to indicate that a person can feel, for example, both happy and unhappy or both aroused and sleepy at the same time. Based on these results, the affect scales most commonly used today were constructed to assess monopolar factors (e.g., Izard, 1972; McNair, Lorr, & Droppleman, 1971; Nowlis, 1965; Thayer, 1967), although several scales continue to be based on bipolar dimensions (e.g., Mehrabian & Russell, 1974; Spiel-

berger, Gorsuch, & Lushene, 1970; Zuckerman & Lubin, 1965).

Bipolarity of Semantic Space

Interestingly, a similar controversy arose in the semantic differential literature. Osgood, Suci, and Tannenbaum (1957) found that the affective meaning of words could be adequately summarized by three bipolar dimensions: evaluation, activity, and potency. Since each of these dimensions was defined by adjective-pair scales such as good–bad, fast–slow, and strong–weak, respectively, Green and Goldfried (1965) argued that bipolarity had been assumed, indeed had been forced onto the results, by the rating procedure employed. Green and Goldfried then attempted to empirically test the assumption of bipolarity by constructing a single-adjective version of Osgood's semantic differential scales and examining the actual correlation between alleged opposites. If evaluation, say, were indeed bipolar, one would expect a high negative correlation between responses to negative evaluation words such as *bad* and those to positive evaluation words such as *good*. In fact, Green and Goldfried generally failed to find such correlations and concluded that semantic space should *not* be conceptualized as bipolar. If accepted, such a conclusion would have important implications not only for the widely used semantic differential technique but for the area of affect as well, in that the semantic differential factors have been interpreted as reflecting basic dimensions of human affect (Osgood, 1969).

Green and Goldfried's (1965) argument against bipolarity of semantic space did not go unchallenged, however. Bentler (1969) argued that high negative correlations indicative of bipolarity might have been obscured in their study by acquiescence, which is an individual-difference variable in the tendency to agree or disagree with an item regardless of its content. That is, if acquiescence were a factor in Green and Goldfried's data, it would have shifted all observed correlations between words in a positive direction and hence away from showing bipolarity ($r = -1.0$). Bentler tested his hypothesis by constructing a single-adjective version of the semantic differential and using a partial correlation technique to control acquiescence. The results provided striking evidence for his hypothesis. For example, a composite of positive evaluation words correlated only .03 with a composite of negative evaluation words—before acquiescence was taken into account. After acquiescence was partialed out, these composites correlated −.76, thus giving strong evidence for the bipolarity of semantic space.

Bipolarity of Affective Space

In the domain of affect, Meddis (1972) has recently defended the notion of bipolar dimensions. He noted two potential sources of bias in the response format used by Nowlis (1965), and subsequently by Thayer (1967), that could account for their failure to obtain bipolar dimensions. The response rating scale used by Nowlis and Thayer, shown in Table 1, assigns 1 point to "No (definitely not)," 2 points to "? (cannot decide)," 3 points to "V (feel slightly)," and 4 points to "VV (definitely feel)." First, Meddis noted, this scale is asymmetric, in that there are two categories of acceptance (V and VV) but only one of rejection (No), and, second, the option "? (cannot decide)" may preclude even ordinal data, since a response to that option could mean a variety of things other than a feeling whose intensity is somewhere between the two neighboring categories.

Meddis (1972) empirically contrasted the results obtained using Nowlis's and Thayer's response format with results obtained using a format that was more symmetric and that excluded the "cannot decide" alternative. (This last format is shown in Table 1 as the "Meddis" format.) Responses to affective adjectives were gathered with each of these formats separately and factor-analyzed. As predicted, predominantly monopolar factors tended to emerge from the data gathered with Nowlis's and Thayer's format, whereas bipolar factors tended to emerge from the data gathered with the Meddis format. When, for example, responses to 38 adjectives similar to those studied by Thayer (1967) were gathered with the Meddis format, bipolar factors were obtained: general activation ver-

sus deactivation-sleep and high activation versus general deactivation. In Meddis's (1972) words, "Whether or not we obtain bipolar factors appears to depend upon the kind of rating scale we use" (p. 183).

Additional Factors Operating Against Bipolarity

Many of the studies supporting monopolarity reviewed above did not employ Nowlis's and Thayer's response format and therefore are not subject to Meddis's specific criticisms. The conclusion of monopolarity in these additional studies may be questioned on the grounds of other methodological problems, however, such as the possibility of alternate rotations and of the influence of difficulty factors (unequal response distributions of the variables involved) in factor-analytic solutions. More importantly, these studies may also have included biases specifically against bipolar factors. First, to the extent that the sample of emotion words studied underrepresents one end of a bipolar continuum, bipolar factors are less likely to emerge. Second, if the instructions ask subjects how they felt over an extended period of time (such as over a week; e.g., Bradburn, 1969; Hall, 1977), they may describe several, perhaps opposite, emotional experiences. Finally, the correlation between two items of a scale has been shown to be spuriously inflated in proportion to the proximity of the items to each other in time or space (Guilford, 1954; Stockford & Bissell, 1949). This phenomenon, known as proximity error, would be expected to result in an overall shift toward more positive correlations among a set of items—irrespective of content—to which subjects responded within a short period of time, which of course is standard practice (and, it would seem, a necessity) when measuring affect.

In short, although numerous empirical studies of affect have concluded against bipolarity, results from these studies may have been biased by one or more of the following: an acquiescence response bias; a response format that fails to yield ordinal data; an asymmetric response format; inadequate sampling of affect terms; instructions to describe feelings during a time period long enough that several, possibly opposite, feelings might have occurred; and a proximity error, which is the tendency to respond similarly to items that are nearer in time or space.

Overview of the Present Study

In the present study, subjects described their current affective state on separate scales assessing opposite ends of hypothesized bipolar dimensions so that correlations between these scales could be empirically established. Four response formats (shown in Table 1) were employed: Meddis's (1972) format plus three others that have been extensively used in studies obtaining monopolar factors of affect, Nowlis's (1965) and Thayer's (1967), McNair and Lorr's (1964), and a true–false format.

To ensure an adequate sample of affect terms, items were chosen for the questionnaire that appeared on a priori grounds to assess primarily opposite ends of pleasure–displeasure, arousal–sleepiness, and dominance–submissiveness, since these dimensions have been suggested by a variety of sources of evidence as basic dimensions of affect (see Russell, 1978, for a brief review of this evidence). All adjectives from Thayer's (1967) four scales of activation were also included in order to explore the activation/arousal dimension more thoroughly. Thayer (1970) showed his scales to be significantly related to physiological indexes of arousal, and the relation of his four factors to the entire affective space is thus of considerable theoretical importance. Moreover, evidence provided by Russell and Mehrabian (1977) indicated that it was possible to subsume Thayer's four dimensions within a more general, three-dimensional theory of affect defined by pleasure–displeasure, degree of arousal, and dominance–submissiveness. The present study provided further evidence on that notion and tested Meddis's (1972) hypothesis that Thayer's general activation is the bipolar opposite of deactivation-sleep and that high activation is the bipolar opposite of general deactivation. Finally, a set of adjectives that

Table 1
Response Probability for Each Category of Four Response Formats

Format	Label			
Meddis (1972)	XX (definitely do not feel) .17	X (do not feel) .41	V (slightly feel) .34	VV (definitely feel) .08
Nowlis (1965) & Thayer (1967)	No (definitely do not feel) .45	? (cannot decide) .15	V (feel slightly) .32	VV (definitely feel) .08
McNair & Lorr (1974)	1 (not at all) .41	2 (a little) .36	3 (quite a lot) .18	4 (extremely) .05
True–false	N (no, I do not feel) .63	Y (yes, I do feel) .37		

Note. Probabilities were calculated across 58 items and 150 subjects for each response format.

appeared to assess depression was included, since on inspection of Thayer's items, depression seemed more likely to be the actual bipolar opposite of his general activation scale.

Method

Subjects

Subjects were 71 female and 79 male University of British Columbia undergraduates. These were students from two different psychology classes who responded to a series of four questionnaires during class time, each questionnaire on a separate day, approximately 2 weeks apart. One class responded in the fall of 1976, the other in the following spring. Ten additional subjects began, but failed to complete the study, and their data were excluded from analysis.

Materials

Eleven sets of adjectives, a total of 58 items, were used. The first 4 sets are Thayer's (1967) factors of activation, and the remaining 7 were constructed a priori to measure pleasure, displeasure, arousal, sleepiness, dominance, submissiveness, and depression. The sets were the following:

1. *General activation* (Thayer): lively, active, full of pep, energetic, peppy, vigorous, activated.
2. *High activation* (Thayer): clutched up, jittery, stirred up, fearful, intense.
3. *General deactivation* (Thayer): at rest, still, leisurely, quiescent, quiet, calm, placid.
4. *Deactivation-sleep* (Thayer): sleepy, tired, drowsy.
5. *Pleasure:* contented, happy, satisfied, pleased, joyful.
6. *Displeasure:* discontented, unhappy, dissatisfied, displeased, joyless.
7. *Arousal:* wide awake, aroused, aflame, impassioned, alert, roused.
8. *Sleepiness:* inactive, half asleep, slow, unaroused.
9. *Dominance:* dominant, controlling, influential, important, autonomous.
10. *Submissiveness:* submissive, controlled, influenced, awed, guided.
11. *Depression:* depressed, discouraged, gloomy, sad, blue, sluggish.

Four questionnaires were formed by intermixing these 58 items in two random orders and then counterbalancing each. Each questionnaire began with directions stating, "On this sheet you will find a list of words or phrases that describe different kinds of moods and feelings. Please use this list to describe your feelings *today*."

Next followed one of the four response formats (shown in Table 1). The true–false format allows two response alternatives; the remaining three formats allow four response alternatives and differ only in the verbal label attached to each alternative. For convenience, these three formats were labeled in the table by the name of investigators who introduced, or at least have used, that format in studies of affect.

Procedure

Each subject responded to the 58-item questionnaire at the beginning of class and returned it to an envelope; all envelopes were collected. Altogether, each subject responded four times, once to each of the four response formats in random order. Each subject responded only once, again in random order, to each of the four orders of presentation of the 58

items. In other words, all possible combinations of response format with order of item presentation were employed and randomly assigned to subjects. No feedback from their data was given to subjects until after the last questionnaire had been completed.

Results and Discussion

Response Format

Table 1 shows the mean probability of a response to each category of each response format. The Meddis format resulted in a roughly even, symmetric distribution of responses. The Nowlis and Thayer format, in contrast, resulted in a bimodal distribution, because subjects avoided the category labeled "? (cannot decide)"—a finding that supports the view that this category may preclude ordinal data. The McNair and Lorr format resulted in a skewed distribution, because the modal response was to the first category, "not at all." Thus, of the four formats studied, the Meddis format provided the best distribution of responses and may be preferred on these grounds alone.

It had been hypothesized that in comparison with the Meddis format, the other formats would shift correlations among items in the positive direction. A sign test was thus used in which each interitem correlation from the Meddis format was compared with its counterpart from each of the other three formats. As expected, correlations based on the other formats did tend to be greater than their counterparts based on the Meddis format: In the Nowlis and Thayer format data, 649 correlations were smaller and 1,004 were greater ($z = 8.71$, $p < .01$); in the McNair and Lorr format data, 684 were smaller and 969 greater ($z = 6.98$, $p < .01$); and in the true–false format data, 500 were smaller, and 1,153 greater ($z = 16.04$, $p < .01$). In addition, the true–false format resulted in more correlations that were greater than their counterparts not only from the Meddis format but from the others as well; Compared with the Nowlis and Thayer format data, 559 were smaller and 1,094 were greater ($z = 13.13$, $p < .01$); and compared with the McNair and Lorr format data, 641 were smaller and 1,012 were greater ($z = 9.10$, $p < .01$). There was no significant difference between correlations from the Nowlis and Thayer format and those from the McNair and Lorr format (864 smaller and 789 larger, $z = 1.82$, *ns*). In sum, when compared with the Meddis format, the three formats commonly used in studies of affect resulted in correlations shifted in the positive direction—away from evidence of bipolarity.

Content Scales

Reliability. Since 7 of the 11 scales were constructed ad hoc for this study, their internal consistency was unknown. Rather than use an extensive item-selection process, however, it was decided to simply eliminate any item from a scale if it failed to correlate positively with each of the other items on that scale. Based on data gathered with the Meddis format ($N = 150$), only one item—"controlled" on the submissiveness scale—failed this criterion, and that item was excluded from further analyses. Measures of internal consistency reliability (coefficient alpha, Cronbach, 1951) were then calculated for all 11 scales, separately for each format. (Values for 5 scales are reported later in Table 3.) Three scales showed only moderate reliability: high activation (.59 to .69), dominance (.68 to .73), and submissiveness (.56 to .65). But, all other scales showed adequate reliability (.70 to .95), and at this point, all scales were retained for further analysis.

Product-moment correlations. Table 2 gives zero-order correlations of 6 scales with hypothesized bipolar opposites, separately for each response format. Correlations between pleasure and displeasure ranged from −.43 with the true–false format to −.71 with the Meddis format. Similarly, correlations between arousal and sleepiness ranged from −.45 with the true–false format to −.62 with the Meddis format. Correlations between dominance and submissiveness were considerably lower and mostly positive, ranging from .27 with the true–false format to −.05 with the McNair and Lorr format. Correlations between Thayer's high activation and its hypothesized opposite, general

Table 2
Association Between Scales and Their Hypothesized Opposites

Scale	Hypothesized opposite	Meddis (1972) r	Meddis (1972) Partial r	Meddis (1972) Partial AQ	Nowlis (1965) & Thayer (1967) r	Nowlis (1965) & Thayer (1967) Partial r	Nowlis (1965) & Thayer (1967) Partial AQ	McNair & Lorr (1964) r	McNair & Lorr (1964) Partial r	McNair & Lorr (1964) Partial AQ	True–false r	True–false Partial r	True–false Partial AQ
Pleasure	Displeasure	−.71*	−.78*	#	−.66*	−.80*	#	−.66*	−.78*	#	−.43*	−.71*	#
Arousal	Sleepiness	−.62*	−.71*	#	−.62*	−.76*	#	−.55*	−.72*	#	−.45*	−.66*	#
Dominance	Submissiveness	.12	.05		.13	.02	#	−.05	−.19	#	.27*	.06	#
General activation	Deactivation-sleep	−.53*	−.50*		−.58*	−.66*	#	−.50*	−.55*	#	−.38*	−.52*	#
General activation	Depression	−.58*	−.60*		−.42*	−.50*	#	−.39*	−.56*	#	−.20	−.43*	#
High activation	General deactivation	−.31*	−.36*	#	−.16	−.30*	#	−.16	−.25*	#	−.14	−.34*	#

Note. r refers to zero-order correlations between the two scales listed. Partial r refers to a partial correlation with acquiescence partialed. The column AQ indicates (by the appearance of a number sign, #) that acquiescence correlated significantly ($p < .01$) with the first scale listed partialing the hypothesized opposite. $N = 150$.
* $p < .01$.

deactivation, were negative, but low and mostly nonsignificant. There were two hypothesized opposites for Thayer's general activation scale: Thayer's deactivation-sleep scale and the depression scale. Correlations between high activation and these two hypothesized opposites were negative and mostly significant, but again modest in size.

To test the hypothesis that response format influenced the correlation between hypothesized opposites, each of the six correlations from the Meddis format was compared with its counterpart from each of the other three formats.[1] Two pairs of correlations were found to be significantly different: (a) The correlation between pleasure and displeasure (−.71) from the Meddis format differed from that (−.43) from the true–false format ($z = 3.85$), and (b) the correlation between general activation and depression (−.58) from the Meddis format differed from that (−.20) from the true–false format ($z = 4.08$). Thus, the true–false response format resulted in two significant differences, both in the expected direction of a more positive correlation than that produced by the Meddis format. In the other four comparisons between these two formats, the differences were in the same direction, although not significant. The Meddis format did not, however, produce any significantly more negative correlations between opposites in comparison with either the Nowlis and Thayer or the McNair and Lorr formats. Indeed, as shown in Table 2, although 9 of these 12 comparisons were in the expected direction, there were no large differences among corresponding correlations from the four-place formats. Contrary to Meddis's (1972) hypothesis, these results suggest that the Nowlis and Thayer format contributes at most a modest bias against obtaining bipolar dimensions.

The Role of Acquiescence

Partial correlations. A clearer picture of the relationship between hypothesized opposites emerged when acquiescence was taken into account through partial correlation. For each pair of scales within a given format, an acquiescence score was calculated for each subject by summing his or her responses to all items (many of them antonyms), except those items constituting the pair of scales to be correlated. For example, the acquiescence score partialed from the correlation between

[1] A separate test was carried out for each of the six pairs of scales listed in Table 2 for a total of 18 comparisons. Each test was conducted at the .001 level (one-tailed) so that the probability of a single spuriously significant result would be kept to approximately .018 (18 × .001). The test used here for the difference between two correlations based on the same sample is discussed in Olkin (1967), but the formula is misprinted there. The correct equation was supplied by James H. Steiger through personal communication.

pleasure and displeasure consisted of responses to 48 items, which were all the items except those for pleasure or displeasure. A partial correlation was then calculated between each pair of hypothesized opposites, partialing the appropriate acquiescence score. These results are also shown in Table 2.

In all but one case (general activation/deactivation, Meddis format), partialing acquiescence shifted the correlation in the expected, negative direction, that is, in the direction supporting bipolarity. In order to assess whether acquiescence contributed significantly to the variance in the content scales, another partial correlation was calculated: the correlation of acquiescence with the first scale listed in the table, partialing its hypothesized opposite. A number sign (#) is shown in Table 2 in the column labeled AQ (acquiescence) whenever this partial correlation was significant at the .01 level, which occurred in 21 of the 24 cases. Interestingly, all three exceptions occurred with the Meddis-format data, suggesting that this format is less subject to acquiescence bias than the others. In contrast, the results for the true–false format were not only significant but sizable, suggesting that this format is particularly subject to acquiescence bias.

Pleasure and arousal. Returning to the partial correlations between content scales, we can see from Table 2 that for pleasure and displeasure, these partial correlations were quite substantial—negative and large in magnitude, ranging from −.71 to −.80. This was the case even for the data from the true–false format, in which was seen the most dramatic change due to partialing acquiescence. Similar results were obtained for arousal and sleepiness, for which the partial correlations ranged from −.66 to −.76. Thus, for these two dimensions, strong evidence of bipolarity was obtained by partialing acquiescence—regardless of which response format was involved.[2]

Dominance. Partialing acquiescence from the correlations between dominance and submissiveness shifted these correlations in the expected negative direction. Nevertheless, the final results, ranging from .06 to −.19, did not differ significantly from zero and provided no evidence of bipolarity. In light of the results for pleasure and displeasure and for arousal and sleepiness, this finding is puzzling. Its explanation seems to be that there was little valid variance in either of the two scales, but especially submissiveness. First, reliabilities for these scales were low. Second, a substantial proportion of the reliable variance appears to have been actually acquiescence response style: Correlations of dominance with an acquiescence score (based on all items except dominance or submissiveness ones) ranged from .20 (Meddis format) to .42 (true–false format); correlations of submissiveness with the same acquiescence score ranged from .32 (McNair and Lorr format) to .52 (true–false format). In short, a considerable proportion of the variance in each scale was either unreliable or invalid, leaving so little valid variance that meaningful conclusions are precluded.

Thayer's scales and depression. Thayer's (1967) four scales yielded intermediate results. The partial correlations for general activation and its two hypothesized opposites, depression and deactivation-sleep, ranged from −.43 to −.66, indicating a consistently negative relationship, although not a substantial one. The partial correlations for high

[2] Since my concern was with the bipolarity of theoretical dimensions rather than with practical prediction problems, a correction for attenuation (unreliability) provided a useful estimate of what these partial correlations would be if the two scales correlated were perfectly reliable. The pleasure–displeasure partial correlation from the Meddis–format data (−.78) was thus corrected for unreliability (as estimated by alpha coefficients) in both the pleasure and displeasure scales; the result was −.88. A similar procedure for the arousal–sleepiness partial correlation (−.71) yielded an estimate of −1.02. Such corrected correlations must be interpreted with caution, because the use of coefficient alpha as an estimate of reliability can overcorrect the correlation (as obviously happened in the case of arousal–sleepiness). Also, it is not a common practice to disattenuate *partial* correlations, although doing so would appear to be biased on the conservative side, since after partialing reliable variance, error variance would constitute a relatively greater proportion of the remainder. Nevertheless, these results at least reinforce the view that as various sources of bias and error are removed, the correlation between these hypothesized opposites approaches −1.00.

Table 3
Multiple Regression Results and Reliability Coefficients for Thayer's Four Scales and Depression

Criterion	Response format	Standardized regression weight			R	Reliability for criterion
		Pleasure	Arousal	Acquiescence		
General activation	Meddis[a]	.32	.67	.08	.84	.91
	Nowlis[b] & Thayer[c]	.19	.75	.16	.84	.92
	McNair & Lorr[d]	.30	.72	.16	.87	.95
	True–false	.15	.67	.24	.80	.93
High activation	Meddis	−.64	.38	.32	.68	.65
	Nowlis & Thayer	−.39	.40	.37	.57	.59
	McNair & Lorr	−.52	.37	.35	.68	.69
	True–false	−.42	.35	.55	.72	.66
General deactivation	Meddis	.43	−.69	.14	.57	.78
	Nowlis & Thayer	.35	−.58	.33	.49	.76
	McNair & Lorr	.27	−.60	.34	.48	.71
	True–false	.28	−.59	.34	.47	.81
Deactivation-sleep	Meddis		−.66	.23	.66	.88
	Nowlis & Thayer		−.83	.29	.77	.90
	McNair & Lorr		−.80	.29	.71	.92
	True–false		−.81	.42	.74	.88
Depression	Meddis	−.82	−.16	.22	.90	.88
	Nowlis & Thayer	−.79	−.22	.33	.87	.84
	McNair & Lorr	−.74	−.28	.40	.84	.90
	True–false	−.69	−.23	.51	.81	.84

Note. Each regression equation was based on 150 cases. All values of regression weights and multiple correlations that are entered were significant at the .01 level. Reliability of each criterion was estimated by Cronbach's (1951) coefficient alpha measure of internal consistency.

[c] 1967.
[d] 1964.

activation and its hypothesized opposite, general deactivation, ranged from −.25 to −.36, indicating a more modest but still negative relationship. Thus, although inversely related, Thayer's scales did not form exact bipolar opposites as Meddis (1972) had predicted.

A Bipolar Affective Space

Regression analyses. The results so far were far clearer for pleasure and displeasure and for arousal and sleepiness than for Thayer's four scales and depression. A series of multiple regression analyses helped to clarify the relationships among the latter five scales and their relationship to pleasure–displeasure and arousal–sleepiness as well. Multiple regression analysis was used specifically to test the hypothesis that pleasure–displeasure and arousal–sleepiness can adequately account for Thayer's four scales and depression.

To define variables for the equations, scores on all scales were first standardized ($M = 0$; $SD = 1$). Displeasure scores were then subtracted from pleasure scores, and sleepiness from arousal, to form pleasure–displeasure and degree-of-arousal predictor variables. For the third predictor variable, a separate acquiescence score was computed for each regression equation by summing scores on all items other than the items on those scales already part of that equation

eparate multiple regression equations were hen computed from data for each response ormat for five criterion variables: each of hayer's four scales plus depression. The esults are shown in Table 3.

Multiple correlation coefficients were shrunken" to provide estimates of the cor- elations in the population between the scores n the criterion predicted from the equation nd those actually obtained. These multiple orrelations were substantial and significant ($p < .01$) in every case. Since unreliability n either the criterion or the predictors limits he possible magnitude of the multiple cor- elation coefficient, the last column of Table 3 provides reliability estimates for each cri- terion variable. As can be seen, the multiple correlations for all scales except Thayer's general deactivation generally approached the limit set by the reliabilities.

A reinterpretation of Thayer's activation dimensions. The standardized regression weights shown in Table 3 provided definitions for the five criterion variables that consider- ably clarified their meaning. Approximately the same information is also shown graphi- cally in Figure 1, which presents loadings of the 11 affective scales on their first two prin- cipal components, since these components

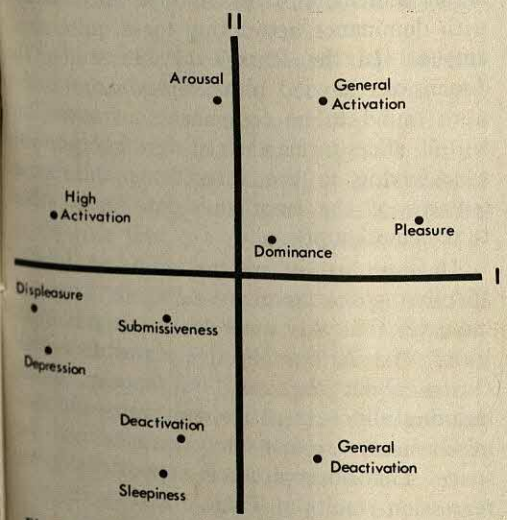

Figure 1. First two principal components of the 11 affective scales, based on data gathered with the Meddis (1972) response format ($N = 150$), after an orthogonal varimax rotation.

were readily interpretable as pleasure–dis- pleasure and degree of arousal. Both analy- ses showed Thayer's high activation and gen- eral activation to contain the expected high degree of arousal. The difference between these two scales, however, was as much the amount of pleasure as it was the degree of arousal, with general activation involving pleasure and high activation involving dis- pleasure. Similarly, Thayer's deactivation- sleep and general deactivation scales con- tained the expected low arousal, but again the two scales differed on pleasure, with gen- eral deactivation involving pleasure but de- activation-sleep involving only arousal. In short, Thayer's (1967, 1970) factor-analytic results were multidimensional not because the arousal continuum is multidimensional but because (among other things) his items varied on the pleasure dimension as well as on arousal.

In Figure 1, general activation is shown to be the *approximate* bipolar opposite of both deactivation-sleep and depression (as was suggested by the partial correlations of Table 2). General activation fell within the high pleasure/high arousal quadrant. Its hy- pothesized opposites, deactivation-sleep and depression, both fell within the opposite quadrant (displeasure/low arousal), but neither fell exactly opposite general activa- tion. The regression equations of Table 3 similarly showed deactivation-sleep to involve too little, and depression too much, displea- sure to be the precise bipolar opposite of general activation, thus explaining the mod- erate magnitude of their negative correlations shown in Table 2.

Similarly, Thayer's high activation fell within the displeasure/high arousal quadrant, and its hypothesized opposite, general deac- tivation, fell within the opposite quadrant, high pleasure/low arousal. These two scales were only slightly negatively correlated rather than exact bipolar opposites, how- ever, because each is maximally saturated with a different factor: High activation is mainly displeasure with a moderate compo- nent of arousal; general deactivation is mainly low arousal with a moderate com- ponent of pleasure.

Even though Thayer's four scales did not form exact bipolar opposites, the results summarized in Figure 1 and Table 3 show that they are part of a bipolar space. Presumably, their exact bipolar opposites could be found if adequate terms were included in the sample of terms studied. From this point of view, Thayer's scales are considerably mislabeled. Since both general activation and general deactivation involve pleasure, "general" could be more precisely replaced with "pleasant." More specifically, general activation assesses high pleasure combined with high arousal and, with items such as *lively* and *vigorous*, could be relabeled "vigor" or "excitement." General deactivation assesses high pleasure combined with low arousal and, with items such as *calm* and *placid*, could be relabeled "calmness" or "relaxation." Deactivation-sleep (with items *sleepy, tired, drowsy*) is appropriately labeled, but high activation assesses displeasure combined with high arousal and, with items such as *jittery* and *clutched up*, could be relabeled "distress."

Implications

As the obscuring influence of methodological biases was reduced in this study, it could be seen that a *bipolar affective space*, defined by pleasure–displeasure and degree of arousal, was able to represent the relationships among scales of pleasure, displeasure, arousal, sleepiness, depression, and Thayer's (1967) four factors of activation. Evidence from a previous study (Russell & Mehrabian, 1977) showed that an even greater range of affective states could be represented in the same way. In a series of regression analyses similar to those shown in Table 3, pleasure–displeasure and degree of arousal were found to account for almost all of the reliable variance in a sample of 42 commonly used scales of affect (e.g., scales of happiness, elation, anger, fear, anxiety, and depression). In another study (Russell, 1978), it was shown that the same dimensions of pleasure and arousal have emerged as the two major dimensions of affect from studies of verbal self-report, semantic differential ratings, successive-intervals scaling, and multidimensional scaling of affect terms. In other words, diverse sources of evidence are converging on a representation of affect similar to that depicted in Figure 1.

This proposed bipolar affective space may appear incomplete, however, because it is characterized by only two dimensions. Indeed, evidence has consistently confirmed the existence of dimensions of affect independent of pleasure and arousal. For example, in the Russell and Mehrabian (1977) study, dominance–submissiveness accounted for a significant proportion of the variance in scales of affect beyond that accounted for by pleasure and arousal. In the Russell (1978) study, multidimensional scaling of affect terms was used to examine more closely the dimensions of affect beyond pleasure and arousal. Results provided evidence for at least three such dimensions, interpreted as dominance/potency/control, depth or importance, and locus of causation.

Nevertheless, I would argue against the use of more than two orthogonal dimensions in a conceptualization of affect. The dimensions beyond pleasure and arousal have consistently been found to differ from pleasure and arousal in several important ways. In the Russell and Mehrabian (1977) study, pleasure and arousal accounted for by far the major proportion of variance in affect scales, with dominance accounting for a quite small amount. In the Russell (1978) study, the dimensions beyond pleasure and arousal (a) were found to be components of some, but not all, affect terms and (b) were interpretable as referring to the antecedents and consequences of the emotional state rather than to the emotion per se.

An examination of the proposed bipolar affective space as represented in Figure 1 indicates that this space lacks "simple structure." The various affective states do not all cluster about the axes, but appear to fall meaningfully (except for dominance and submissiveness) around the perimeter of the space. This observation is supported by the regression results of Table 3 and by those of Russell and Mehrabian (1977), in which affective states were typically found to be defined as *combinations* of pleasure–displeasure and degree of arousal. It may be arbitrary

erefore, where the axes are located within is space. For example, a 45° rotation of e axes shown in Figure 1 would yield two polar axes that could be labeled "excite-ent–depression" and "distress–relaxation." lore generally, the placement of the various fective states in relation to each other within e space appears to be more meaningful than e placement of the axes within the space.

The proposed bipolar affective space raises nother issue concerning the conceptualiza-ion of affect. The proposed space is based n a definition of the domain of affect that ncludes low arousal states, such as sleepi-ess and relaxation, which are not commonly ncluded on psychologists' lists of the emo-ions. For example, Tellegen [3] defines affect s *aroused feelings*. His proposed conceptual-zation of affect, which involves two dimen-sions, positive affect and negative affect, would therefore be expected to fall solely within the high arousal quadrants of Figure 1. And, indeed, his two dimensions appear to roughly correspond to the rotated dimensions of excitement and distress, respectively, de-fined above. The bipolar opposites of Tel-legen's dimensions, however, fall outside the domain of aroused feelings. Tellegen's dimen-sions therefore ought *not* to be bipolar within that domain, and this appears to be his con-clusion.

The present evidence showed that an em-pirical relationship exists between high and low arousal states and, therefore, that it is meaningful to group the two together within the same domain. The Russell and Mehrabian (1977) study suggested the same conclusion by showing that low arousal states were de-finable by the same pleasure and arousal di-mensions required to define the high arousal states. From my point of view, a fully ade-quate description of a person's affective state at any moment in time therefore must in-clude the possibility of these more mundane, but frequently encountered, low arousal states as well as the more dramatic emotions.

[3] Tellegen's conceptualization is described in Hall (1977) and was further elaborated through per-sonal communication. Needless to say, only the roughest approximation to his conceptualization is presented here.

The Generalizability of Salience Effects

Shelley E. Taylor, Jennifer Crocker, Susan T. Fiske,
Merle Sprinzen, and Joachim D. Winkler
Harvard University

Stimuli that engulf attention often have a disproportionately large impact on the judgment process, even when logically irrelevant. The boundary conditions of such salience effects were examined in a scenario where subjects observed a dyadic conversation in which the visual prominence of one or another participant was manipulated. Two hypotheses were examined: (a) Salience effects are dependent on quantity of information encoded and disappear at low levels of attention, and (b) salience effects will disappear if higher involvement in the situation serves to heighten and focus attention on more relevant cues. Neither hypothesis was supported. Rather, salience effects continue to be found (a) when the perceiver is distracted, (b) whether the perceiver's impressions are assessed immediately or after a delay, (c) when the conversation has high interest value, (d) regardless of the perceiver's cognitive tuning set, and (e) when the perceiver is involved in the discussion. We conclude that salience effects are highly generalizable and that they have a significant impact on both trivial and important social judgments. We suggest that salience effects are not customarily under the control of the social perceiver, but may rather be automatic.

Considerable research leads to the conclusion that logically uninformative, irrelevant, but salient social stimuli have a disproportionately large impact on the judgment process (see Taylor & Fiske, 1978, for a review). In general, the form of this "salience" effect is that people attribute causality to stimuli that engulf their attention. Taylor and Fiske (1975), for example, found in two separate studies that when one's attention is engulfed by a particular person in the environment, one sees that person as the causal agent in the conversation. Storms (1973) found that when an individual's own behavior or that of another person is made salient via videotaped playback, the salient information is a strong influence on judgments of causality. Duval and Wicklund (1972) found that the self is perceived as more of a causal agent when attention is self-focused than when it is not, and subsequent research has upheld this finding (see Wicklund, 1975; see also McArthur & Post, 1977).

Since the early studies that focused on judgments of causality, it has emerged that salient stimuli may have an impact on perceptions other than causal ones. Specifically, it appears that the evaluative qualities of salient stimuli are exaggerated, more is learned about them, they are perceived as more representative of their social group, and they are more "available," that is, more easily brought to mind (Tversky & Kahneman, 1974).[1] (See

[1] Some studies (e.g., McArthur & Post, 1977; Storms, 1973) suggest that salient people's behavior is more likely to be perceived as dispositionally rather than situationally based. However, the evidence on this point is equivocal (see Taylor and Fiske, 1978).

Taylor & Fiske, 1978, for a review of the literature on these points.) Taylor, Fiske, Close, Anderson, and Ruderman (Note 1), for example, found that a black (in an otherwise white group), male (in an otherwise female group), or female (in an otherwise male group) drew off a disproportionate amount of attention, was perceived as being more prominent and influential, was evaluated more extremely, and was somewhat more stereotyped (perceived as representative) than was a comparable individual in a racially or sexually mixed group. Several studies have found that more information is retained about a salient other (e.g., McArthur & Post, 1977; Taylor & Fiske, 1975). Pryor and Kriss (1977) found that salient items in sentences (subjects as opposed to objects) were both more available (i.e., recalled faster, though not better) and perceived as more causal.

Salience effects are of more than theoretical interest. They have been posited as the mediators of a number of important social processes. Taylor et al. (Note 1), for example, have suggested that the salience of a novel stimulus helps explain reactions to a solo black, a solo woman, or a solo man in a token integration situation. Wicklund (1975) has suggested that self-esteem is influenced by whether the self is salient. The salience of particular cognitions affects people's social judgments and self-perceptions (e.g., Kiesler, Nisbett, & Zanna, 1969; Ross, Lepper, & Hubbard, 1975). Salience explanations have been proferred for emotional disorders such as test anxiety (Wine, 1971) and stuttering (Storms & McCaul, 1976). However, the boundary conditions around salience effects have yet to be adequately explored.

One hypothesis (Taylor & Fiske, 1975, 1978) is that salience effects depend on some minimal level of attention during exposure to the initial stimulus conditions. According to this hypothesis (Hypothesis 1), salience effects would not be expected to emerge if attention (as indexed by recall) were attenuated.

A second hypothesis (Hypothesis 2), which is in some respects opposite to the first, is that salience effects are characteristic of low levels of intensity of attention and that if a variable were introduced that increased the individual's intensity of attention, salience effects would not emerge. The assumption underlying such a hypothesis would be that people pay attention to trivial but salient stimuli when there is nothing else worth watching more closely, but that when more interesting or informative stimuli are present degree of attention is heightened and focused such that otherwise salient but trivial stimuli are ignored. Such variables might include a high level of interest value in the content of material exchanged or the subjects' involvement in the information exchanged. Since much of the research demonstrating salience effects has been conducted in unarousing, uninvolving, and low information contexts, the question of whether salience effects will generalize to more engrossing, arousing, and involving settings is a very important one (see McArthur & Solomon, 1978).

Hypotheses 1 and 2 are not necessarily incompatible. It may be that some minimum level of attention is required to obtain salience effects, but that at the highly intense levels of attention produced by high degrees of subject involvement, salience effects will disappear.

Three studies were conducted to examine the hypothesized bases of salience effects. In the first, subjects participated in a point-of-view experiment in which their information intake was either severely reduced or not by a distraction task. In the second and third studies, a variety of manipulations was introduced to see if increasing the subject's degree of attention through involvement in the nature of the material exchanged would alter salience effects. Failure to obtain salience effects under conditions of high distraction would constitute evidence for Hypothesis 1. Failure to obtain salience effects under conditions of increased attention would constitute evidence for Hypothesis 2.

Experiment 1

Experiment 1 examined whether salience effects depend on differential encoding of information during exposure to the initial stimulus conditions. In this study, subjects were distracted during either the encoding stage (i.e., when observing the conversation in

which salient information was provided) or the retrieval stage (i.e., when rating the two participants). Crossing these two variables enabled us to see if salience effects represent an encoding or a retrieval bias or a combination of the two.

Method

Subjects

Subjects were 100 Harvard–Radcliffe undergraduates who signed up for a "getting–acquainted" study. They were run in groups of 8 to 9 subjects, with two experimental confederates posing as additional subjects.

When subjects arrived for the experimental session, the experimenter explained that an informal conversation would involve two of them and that the rest of them would be observers. The experimenter "picked" the two (male) confederates to hold the conversation and seated them facing each other, with the other subjects arranged as observers. Four subjects sat behind each confederate, and if a ninth subject was present, that person sat in the control condition. That is, for four subjects, one of the confederates (A) engulfed their visual attention, and for the other four subjects, the other confederate (B) engulfed their visual attention. Control subjects had equal visual access to both confederates. This procedure has been successfully used as a manipulation of salience in previous studies (see, for example, Taylor & Fiske, 1975).

Procedure

The observers were instructed that the experiment was concerned with several specific aspects of the conversation, so that separate instruction sheets would be passed out to each person. Subjects were told that their task might seem odd, but that both psychological and linguistic aspects of interaction were being studied in the experiment. All subjects were told to listen to the conversation without participating in it and without taking notes. For the undistracted condition, the instructions read:

> As you are watching and listening, please observe the conversation in general. Form an impression of the whole discussion. Imagine you are overhearing these people in a public place. Afterwards, we will be asking you about your observations of these people and the entire conversation.

The other half of the subjects received instructions that constituted the encoding distraction manipulation:

> As you are watching and listening, please observe the conversational usage of pronouns. Count the total times I, me, and you are used. Keep a combined score for the conversation as a whole. Afterwards, we will be asking you about your observations of these people and the entire conversation.

The confederates then carried on a "getting–acquainted conversation," as if they had just met. They exchanged information about summer jobs, college major, career plans, hometown, and the like. The experimenter stopped the conversation after they had exchanged the standard information. The confederates were asked to leave and wait down the hall.

At this point, the decoding distraction manipulation was introduced. Half the subjects were seated at chairs with writing surfaces, and they were told to fill out the impression questionnaire. The other half of the subjects were taken into the next room and seated at a large table. The experimenter mentioned that someone else was working in the room, but had said that the subjects could use it. When the subjects entered the room, they found a second experimenter setting up audiovisual materials ostensibly for an unrelated experiment. As these subjects attempted to fill out the dependent measures, the second experimenter continually readjusted the volume of a tape recording, changed and focused colorful slides, and generally bombarded the subjects with distracting audiovisual stimuli.

Dependent Measures

Subjects rated both confederates, and the order of rating (salient first/nonsalient first) was counterbalanced. For each confederate, subjects were asked first to recall what he had said. They then rated how friendly, talkative, and nervous he was, to what extent each of these qualities was dispositionally caused, and to what extent it was situationally caused. The last five questions assessed causal influence in the conversation: To what extent did this person set the tone of the conversation between the two people? To what extent did this person determine what kind of information would be exchanged during this conversation? To what extent did this person cause his partner to behave as he did? To what extent did you form an impression of this person? And, how much did this person influence the conversation as a whole? All responses were on 9–point scales with labeled endpoints.

After subjects had completed recall, dispositional–situational, and conversational causality measures for each confederate, they were asked to report the results of their observation task (if any), for example, the number of pronouns they had counted. They were also asked how successful they felt at the observation task, how much the situation interfered with the observation instructions, and how much the situation interfered with filling out the questionnaire. When they had finished, subjects were paid $2 each and fully debriefed. None expressed suspicion about the study's purpose.

Results

The dependent measures were analyzed by a four–way analysis of variance. The between–subjects variables were encoding distraction (distracted/not), retrieval distraction (distracted/not), and confederate faced (A/B). Confederate rating (A/B) was a within–subjects variable for all measures except the manipulation checks.

Manipulation Checks

On the question assessing the encoding distraction manipulation, subjects who counted pronouns felt that the observation situation (i.e., counting pronouns) interfered significantly more than did undistracted subjects, $F(1, 91) = 4.84$, $p < .03$; Ms = 4.80 vs. 3.72. There were no other significant effects in that analysis.

On the question assessing ease of filling out the questionnaire (the retrieval distraction manipulation check), retrieval distraction subjects reported no more difficulty than no-retrieval distraction subjects; however, retrieval distraction subjects took much longer to fill out the questionnaires than did the no-retrieval distraction subjects. This informal observation indicated that despite the lack of difference on the manipulation check, the manipulation of retrieval distraction may have been successful. (On the other hand, subjects may have circumvented the retrieval distraction manipulation by taking longer.) Interestingly, it was the encoding distraction subjects who showed a difference on this distraction measure, $F(1, 90) = 6.64$, $p < .02$. Apparently, the encoding distraction subjects' difficulty in observing the conversation made them find it hard to answer the questions. This was particularly true for the distracted subjects facing Confederate B, $F(1, 90) = 4.80$, $p < .03$. There were no other significant effects. Finally, the question assessing how successful subjects felt at the observation task, a potential covariate for later analyses, showed no effects at all.

Causality Measures

The five conversational causality measures (set tone, determine information exchanged, cause partner's behavior, influence conversation, form impression) were summed to form a general index of causality, and the analysis showed that the salience effect emerged clearly, $F(1, 91) = 13.29$, $p < .001$. Means are presented in Table 1. Importantly, this effect did not interact with either distraction manipulation, either separately or combined (all Fs < 1). Thus, the data show a simple salience effect, uninfluenced by both distraction manipulations.

Table 1
Causality and Evaluation Ratings: Experiment 1

Condition	Rating			
	Causality index	Friendly	Talkative	Nervous
Facing A				
Rate A	22.58	6.56	6.40	4.73
Rate B	21.80	6.30	4.91	4.90
Facing B				
Rate A	18.85	5.72	5.42	5.10
Rate B	26.11	7.49	5.79	4.06

Note. Causality index values range from 5 to 45; other scales were 9-point rating scales. Higher values indicate greater rated perception. F values for salience interaction effect range from 5.25 to 22.53, with 1 and 75 degrees of freedom; ps range from <.03 to <.001.

In addition to the salience effect, the causality ratings showed a main effect for confederate, $F(1, 91) = 8.65$, $p < .005$, such that one confederate (B) was consistently seen as more causal than the other. This confederate effect accounts for the reversal of the predicted mean pattern in the no distraction–facing A cell, but does not affect the salience results. The question How much did this person talk?—also a measure of prominence—showed salience effects such that the salient actor's estimated talking time was rated higher, $F(1, 92) = 16.90$, $p < .001$. There was also a confederate effect on this measure, $F(1, 92) = 6.16$, $p < .02$.

The dispositional and situational causality measures were summed to form separate scales of each. No salience effects emerged, nor were there any other significant effects.

Recall

There was no effect of salience on recall (F close to zero). However, the encoding distraction (counting pronouns) manipulation resulted in those subjects remembering virtually nothing of the conversation, $F(1, 92) = 20.45$, $p < .001$, compared with subjects who simply observed without any distraction. Recall also showed a main effect for confederate, $F(1, 92) = 45.65$, $p < .001$.

Evaluations

There were two evaluative measures: friendly and nervous. Salience effects emerged on the friendliness rating, $F(1, 92) = 41.76$, $p < .001$, such that the salient actor was seen as especially friendly. Similarly, salience effects emerged on the nervousness rating, $F(1, 91) = 6.24$, $p < .02$, such that the confederate a subject faced was seen as relatively less nervous than the nonsalient confederate. On both personality evaluations, the salient actor's rating differed substantially from the nonsalient actor's rating. Since both means were on the same side of the midpoint, and the salient actor's ratings were always more extreme, this pattern represents an exaggerated evaluation of personality attributes due to salience, a pattern similar to that found in previous studies (Taylor & Fiske, 1978).

Both variables also showed confederate effects: friendly, $F(1, 92) = 23.09$, $p < .001$; and nervous, $F(1, 91) = 3.18$, $p < .07$. Finally, the encoding distraction influenced subjects to rate both confederates as less friendly, $F(1, 92) = 9.51$, $p < .003$.

To summarize, then, salience effects on causality ratings and evaluations were found in this study. The hypothesis that such effects depend on differential encoding of information during exposure to initial stimulus material was not supported, however.

Experiment 2

Experiment 2 was designed as a test of Hypothesis 2: that salience effects are eliminated when degree of attention is heightened and focused by a more engaging or informative setting. In order to examine conditions with high external generalizability, we manipulated intensity of attention by having subjects observe a debate on a current issue with which they were either involved or uninvolved. In addition to examining the usual dependent variable of causality (the main test of the hypothesis), we included secondary measures of persuasiveness, attitudes toward the issue, and attitudes toward the debate to see if they would be affected by salience. Specifically, if salience exaggerates affect, one's beliefs about a debater's persuasiveness, efficacy, and the like should increase when one agrees with the debater's position and he or she is salient, and they should decrease when one disagrees with the debater and he or she is salient.

Method

Subjects

Ninety-one Harvard–Radcliffe undergraduates (46 males, 45 females) participated as paid volunteers and were selected on the basis of their position on the issue debated and the importance of that issue to them. Involvement and position on the issues was assessed by drawing subjects from a pool of participants in an "attitude survey" ostensibly unconnected with the present study and run by a different experimenter. The attitude survey asked participants to indicate their position on each of 34 different issues and to indicate the importance of each issue to them. Two issues were used in the present study: banning cigarettes and alimony for unmarried couples. Subjects selected for the involved conditions rated the issue significantly more important to them ($M = 5.67$ on a 9-point scale) than uninvolved subjects ($M = 2.50$, $t = 13.25$, $p < .001$). There was a small but nonsignificant difference between the involved and uninvolved subjects on their position on the issue, with involved subjects slightly more opposed ($M = 1.38$) than uninvolved subjects ($M = 1.72$, $t = 1.40$, *ns*).

All the survey participants were informed that several people in the psychology department needed subjects for experiments and that they should leave their name and number if they were interested in participating as paid volunteers in studies unconnected to the survey.

Procedure

Survey participants who were opposed on one of the two issues were contacted by telephone and recruited for an experiment on persuasion. The same procedure as in Experiment 1 was used, with the following changes. One involved subject and one uninvolved subject were assigned to each of the three viewpoint conditions. To support the impression that the confederates were simply subjects

assigned to the debater role, the confederates were given 2 minutes to think about and jot down arguments supporting the side of the issue they had been assigned to argue. Two different pairs of confederates assisted with the study, and each confederate argued the "pro" side of the issue in some groups and the "anti" side in other groups.

Dependent Measures

Subjects rated both confederates, and the order of rating (salient first/nonsalient first) was counterbalanced. Subjects were asked to recall all the personal information and arguments that each of the debaters gave.

Subjects then completed 9-point measures assessing which confederate was more causal (To what extent did this person set the tone of the discussion? How much did this person talk in the discussion?); which confederate was more persuasive (How much did this person persuade the other?); replicability of the outcome (If a rematch of this discussion were arranged, how different would the outcome be?); and mutability of the outcome (How likely is it that this person could have said anything different to be more persuasive?). Subjects also judged which confederate had won the argument, which confederate was more convincing, and which one was more thorough.

Finally, the subjects were asked to indicate their position on the issue, and they filled out several manipulation checks (How interesting did you think the discussion was? How much did you care who won the argument? How much do you care about this issue? How personally involved did you feel in the discussion?).

When all the subjects in the group had completed the dependent measures, they were carefully debriefed, asked for their impressions of the study, informed of its purpose, and paid $1.50 each. During the debriefing, two subjects indicated a suspicion that the debaters were actually confederates of the experimenter. When questioned, they indicated no understanding of the hypothesis of the study, so the data from these subjects were included in the analysis. Subjects were asked not to discuss the study with other potential subjects.

Results

Manipulation Checks

Four manipulation checks of involvement were included, and analysis indicated that the involvement manipulation was successful. In response to the question, How much do you care about this issue? involved subjects indicated that they cared significantly more ($M = 4.67$) than uninvolved subjects ($M = 3.01$), $F(1, 78) = 22.94$, $p < .001$. Involved subjects also reported feeling significantly more personally involved in the discussion ($M = 3.53$) than uninvolved subjects ($M = 2.34$), $F(1, 78) = 7.46$, $p < .008$. Differences between the involved and uninvolved subjects were not significant on their ratings of how interesting they found the discussion (involved $M = 3.74$; uninvolved $M = 3.46$), $F(1, 78) = .50$, $p < .49$, or how much they cared who won (involved $M = 2.58$; uninvolved $M = 2.12$), $F(1, 78) = 1.33$, $p < .26$.

Causality Measures

Ratings on two causality measures used in earlier studies (To what extent did this person set the tone of the discussion? and How much did this person talk in the discussion?) were correlated .54 ($p < .001$) and did not correlate higher than .25 with any other dependent variables. Accordingly, a causality measure was created for each confederate by summing the talkativeness and the setting-the-tone ratings. A repeated measures analysis of variance with viewpoint (facing pro, facing con, or control), involvement (2 levels), and issue (2 levels) as the between-subjects factors and person rated (pro or con) as the within-subjects factor was performed on the causality index. The point-of-view effect (Viewpoint × Person Rated) was weak and nonsignificant, $F(2, 79) = 1.022$, $p < .40$. However, the interaction of the point-of-view effect with involvement (i.e., Viewpoint × Person Rated × Involvement) was significant, $F(2, 79) = 4.95$, $p < .01$, and revealed that the point-of-view effect was strong for highly involved subjects but irregular for low-involvement subjects, as the means in Table 2 indicate. There was also a significant Viewpoint × Person Rated × Involvement × Issue interaction on the causality item, which showed that the failure to replicate the point-of-view effect for uninvolved subjects was mainly due to a reversal of the predicted mean pattern for uninvolved subjects in the smoking issue condition only, $F(2, 79) = 3.65$, $p < .04$. Finally, there was a significant main effect for person rated such that subjects rated the person they agreed with (con) as more causal ($M = 7.45$) than the person they disagreed with ($M = 6.51$), $F(1, 79) = 4.90$, $p < .03$.

Table 2
Mean Causality Ratings as a Function of Involvement: Experiment 2

	Involvement			
	High		Low	
	Person rated		Person rated	
Viewpoint	A	B	A	B
Facing A	7.32	6.53	5.88	7.80
Control	7.20	7.40	5.86	6.86
Facing B	5.13	8.69	7.37	7.39

Note. Subjects agreed with Confederate B and disagreed with Confederate A; higher numbers indicate greater causality. Viewpoint × Person Rated × Involvement interaction was significant at $F(2, 79) = 4.95$, $p < .01$.

Recall

Subjects were asked to recall as many of the arguments and personal details given by each confederate as they could. There were no significant salience effects on either recall measure. There was a significant Person Rated × Involvement interaction on recall of arguments such that highly involved subjects recalled more of the arguments they agreed with (the con arguments) ($M = 44.52\%$; $M = 41.91\%$ for pro arguments), whereas uninvolved subjects recalled more of the arguments they disagreed with ($M = 49.87\%$; for pro arguments, $M = 43.50\%$), $F(1,79) = 4.79$, $p < .04$. There were also uninterpretable main effects for issue on several measures that will not be reported here.

Evaluations

No significant salience effects (Viewpoint × Person Rated) or Salience × Involvement interactions emerged on the secondary judgments (persuasiveness, repeatability, mutability, convincingness, thoroughness, winning the argument, and attitude change).

Discussion

Why did salience effects replicate under conditions of high involvement but not under conditions of low involvement? If other point-of-view studies are uninvolving, as we have suggested, this failure to replicate the effect under the low-involvement condition is quite puzzling. One possibility is that the low-involvement condition is less involving than the typical point-of-view study, whereas the high-involvement condition is more involving. Although it is impossible to directly compare the degree of subject involvement across studies, this explanation seems possible. Subjects chosen because they indicated that an issue was not important to them may well be less involved than subjects viewing an exchange of personal information, who may in turn be less involved than subjects viewing a discussion on a topic that they rated as very important to them. Anecdotal support for this explanation is provided by the experimenter's report that involved subjects paid close attention to the arguments and suggested during the debriefing points that the debaters had missed; however, uninvolved subjects spent time looking around the room, playing with their pencils, and generally looking very bored. This explanation, then, suggests that some minimal degree of attention is required to achieve salience effects; that is, the subject must be paying enough attention for the salient information to actually be salient.

While this explanation would seem to contradict the results of Experiment 1, in fact, it does not. The salience manipulation is a visual one (i.e., who engulfs one's visual field). In Experiment 1, though subjects' verbal recall was eliminated, their attention to the salience manipulation did not wane, whereas in Experiment 2, it was the visual attention of low-involvement subjects that seemed to wander. Further research will determine whether this explanation is viable or whether, since the nonreplication occurred in only one of the low-involvement conditions, it is simply a fluke of the stimulus materials.

Experiment 3

Experiment 3 was designed to conceptually replicate and extend the results of Experiment 2 and, by implication, the test of Hypothesis 2. We pursued the issue of whether salience effects (overrated causal role of sali-

ent but trivial stimuli) are eliminated when other factors conspire to heighten and focus attention on more relevant aspects of the situation. In this study, half the subjects were given a cognitive tuning set (Zajonc, 1960) to receive information, and half were given a transmission set to communicate information to others. We reasoned that a transmission set prompts subjects to heighten and focus their attention to information necessary for transmitting a cogent impression (e.g., an individual's behavior) as opposed to salient but trivial information (i.e., his or her visual prominence), whereas a receiving set more closely mirrors the set of subjects in previous studies.

A second issue we explored in Experiment 3 was the effect of timing on salience effects. It may be that when information has been highly salient, its impact on the judgment process is strong only immediately after the experience, when the salient information and the judgment process are in close contiguity, and not if judgments are delayed to a later time. That is, it is possible that following a delay, salient information assumes its rightful, limited role in judgments.

Method

Subjects

Eighty-eight Harvard-Radcliffe students (56 males, 32 females) were scheduled in groups of 6. Subjects were told that the study's purpose was to find out what happens during self-disclosure conversations (that is, how observers form impressions of people who are disclosing characteristics about themselves) and what observers do with information about others at different points in time.

We used a self-disclosure conversation because this kind of conversation is less ritualistic, stylized, and formal than getting-acquainted conversations. In addition, the confederates would be conversing in impression-formation terms; that is, the confederates would be describing themselves in ways that would tend naturally to allow subjects to form impressions. For these reasons, this kind of conversation is more interesting to the subjects than the getting-acquainted conversations used in previous research.

Cognitive Tuning Manipulation

As observers, the subjects were asked to watch a videotape of a self-disclosure conversation while performing a particular task. Sheets of paper were passed out describing the task each was to perform. Half of the subjects in each group were given the "receiver" manipulation:

> Your task as you watch the videotape is to begin to form an initial impression of both of the participants. You should use the information each person provides about himself to begin to think about the kind of people they are. After you have finished watching the videotape, during the second part of the study, you will be receiving additional information about the participants that should help you form better impressions of them both. In other words, your task while watching the videotape is to begin to think about the sorts of people the participants are, impressions that should be clearer after you have received additional information about them during the second part of the study.

The others received the "transmitter" manipulation:

> Your task as you watch the videotape is to form a clear impression of both of the participants. You should use the information each person provides about himself to figure out what kind of people they really are. After you have finished watching the videotape, during the second part of the study, you will be asked to communicate all you can about both people to others. In other words, your task is to determine, from watching their conversation, the sorts of people the participants are in order to communicate your impressions to others during the second part of the study.

When the videotape ended, subjects were asked to write down what their task was, as a manipulation check.

Point-of-View Manipulation

The experimenter told the subjects that the conversation they would be watching had been videotaped during another part of the experiment that had involved subjects having a self-disclosure conversation with other subjects. Subjects were told that cameras had been set up to give a split-screen image, but in the videotaping of the particular conversation they would be watching, one of the cameras had not worked properly; instead of a split-screen picture, they would see one in which only one of the two conversationalists was clearly visible. The subjects then watched a videotape of two male confederates, A and B, ostensibly having a self-disclosure conversation. The videotape for all groups began with a brief introduction in which both confederates could be seen, and then, following a blackout in the film, half of the groups of subjects could only see A over the shoulder of B, whereas the other half of the groups could only see B over the shoulder of A.

The confederates discussed characteristics that they liked and did not like about themselves and characteristics that other people liked and did not like about them. The confederates talked about the same length of time and exchanged similar kinds of

moderately personal information. The conversation lasted about 15 minutes.

Delay Manipulation

After watching the videotape, subjects in the delayed conditions were dismissed; two subjects per group (one receiver and one transmitter) returned after an hour, and two subjects (one receiver and one transmitter) returned after a day. The remaining two subjects per group (one receiver and one transmitter) completed the dependent measures immediately.

The tuning, point-of-view, and delay manipulations produced a fully crossed $2 \times 2 \times 3$ between–subjects design.

Dependent Measures

The experimenter asked the subjects to fill out a questionnaire about the self-disclosure conversation they had observed. Each subject rated both confederates; the order of rating the confederates was counterbalanced. The first part of the questionnaire, for each confederate, was a recall task; subjects were asked to remember what the confederate said that he and others liked and did not like about himself. In the second part, subjects rated how friendly, talkative, and nervous the confederate was, on 9-point scales with labeled endpoints. For each of the three behaviors, the subject also rated the extent to which the behaviors were caused by dispositional qualities of the person (9-point scale) and by situational factors (9-point scale). In the third part, on 9-point scales, subjects rated how much the confederate set the tone of the conversation, was able to draw out more from the other than he had to give up about himself, caused his partner to behave as he did, truly disclosed about himself, and influenced the conversation as a whole. Subjects also rated the degree to which they were able to form an opinion of the confederate, received a favorable impression of the confederate, and liked him. Last, they were asked to rate how easy it was for them to answer the questions in this part of the questionnaire. Subjects then filled out an identical set of questions about the other confederate.

Subjects took approximately 20 minutes to complete the ratings. Subjects were then fully debriefed. The debriefing revealed that subjects were not suspicious about the point–of–view manipulation and did not guess the true nature of the experiment. Subjects took the cognitive tuning manipulation seriously; transmitters used the debriefing to relate their impressions of the confederates, whereas receivers expected to receive additional information. The hypotheses of the experiment were then discussed, and the subjects were paid; subjects in the immediate condition received $2 each, and subjects in the delayed conditions received $3 each.

Table 3
Mean Causality and Evaluation Ratings as a Function of Salience: Experiment 3

Measure	Rating of confederate faced	Rating of confederate not faced
Causality index	14.32	11.76
Talking	5.98	5.32
Recall of positive characteristics	2.95	2.41
Favorable impression	4.50	3.35
Ease of ratings	6.36	5.88
Liking	4.09	3.18

Note. Causality index values range from 3 to 27; other scales are 9-point rating scales. Higher values indicate greater rated perception. F values for salience interaction effect range from 5.25 to 22.53, with 1 and 75 degrees of freedom; ps range from $<.03$ to $<.001$.

Results

Dependent measures were analyzed by analyses of variance using cognitive tuning, confederate faced, and delay as between–subjects factors. Because each subject rated both confederates, confederate ratings were a repeated measure.

Manipulation Checks

The manipulation check verified that the cognitive tuning manipulation had worked for most of the subjects (73 of the 88 subjects remembered their task after they had viewed the videotape).

Causality Effects

On the basis of high average intercorrelations, subjects' ratings of confederates' influence on the tone of the conversation, influence on the conversation as a whole, and influence on partner were combined into a causality index for purposes of analysis.

As Table 3 demonstrates, the salience effect emerged. Subjects perceived that the confederate they observed was more causal in the conversation than the confederate they did not observe, $F(1, 76) = 7.45$, $p < .01$. There were no other interactions or main effects on this causality index. Even when sub-

jects who had not remembered the tuning manipulation were removed, there were no significant cognitive tuning main effects or interactions with the causality index. The question How much did this person talk? is also a measure of prominence and showed similar salience effects, such that subjects perceived the salient confederate as talking more than the nonsalient confederate, $F(1, 75) = 5.25, p < .03$.

Given that the observer has decided who was influencing the conversation, will the observer go on to make situational and personal attributions about why the confederate behaved as he did? As mentioned, for the three behaviors measured—friendliness, talkativeness, and nervousness—subjects indicated how dispositionally caused and how situationally caused each was for each confederate. The analysis revealed that subjects perceived that the nervousness of the confederate they observed was caused less by the personal characteristics of the confederate and more by the characteristics of the situation, whereas they perceived that the nervousness of the confederate they did not observe was caused more by the personal characteristics of the confederate and less by the characteristics of the situation (personal, $F(1, 72) = 8.73, p < .01$; situational, $F(1, 72) = 4.76, p < .03$. This finding constitutes a reversal of the mean pattern predicted by the actor–observer hypothesis (see Storms, 1973). However, because of the nature of the attribute "nervous," it may be that the data pattern is consistent with a view of the salient person as "in charge." [2]

Evaluations

Significant salience effects also emerged on recall of positive characteristics mentioned by the confederate, $F(1, 76) = 22.53, p < .001$; the degree to which the confederate made a favorable impression, $F(1, 76) = 9.30, p < .01$; the ease with which the subject could rate the confederate, $F(1, 76) = 15.39, p < .001$; and how much the subject liked the confederate, $F(1, 76) = 8.18, p < .01$. The means of these measures (see Table 3) revealed that subjects could more easily form impressions, particularly favorable impressions, about the confederate they faced than about the confederate they did not. As in Experiment 1, the salient person's attributes were exaggerated in a positive direction. Confederate effects also emerged on these impression measures, but they are uninterpretable and will not be reported here.

Summary

Experiment 3 found strong salience effects on a wide variety of measures in a self-disclosure situation. However, the impact of cognitive set and whether impressions were assessed immediately or later on the magnitude of those salience effects was negligible.

General Discussion

Three studies examined two hypotheses regarding the effects of salient information on social judgments. The first was that salience effects are dependent on attention and that differential attributions are made to stimuli for which large amounts of information have been gathered. Results indicated that as long as subjects actually attend to the salient information, salience effects occur and are not increased or decreased by more or less retention of information. Indeed, the fact that salience effects occurred even when subjects had taken in virtually none of the verbal information exchanged in the scenario indicates that a very low degree of verbal attention can still produce biased attributions of causality to a visually salient person.

The second hypothesis tested was that salience effects are characteristic of low levels of intensity of attention and that if some varia-

---

[2] There were some uninterpretable interaction effects with some of the measures: (a) a Delay × Cognitive Tuning interaction with talking, because of personal characteristics, $F(2, 75) = 6.32, p < .01$; (b) a Delay × Cognitive Tuning × Person Faced interaction with nervous, because of situational characteristics, $F(2, 72) = 3.14, p < .05$; (c) a Delay × Cognitive Tuning × Salience interaction with how easily the subjects could rate the confederate, $F(1, 75) = 4.62, p < .01$; and (d) a Cognitive Tuning × Person Faced interaction on perceptions of how much the confederate talked, $F(1, 75) = 7.94, p < .01$.

ble that increases intensity of attention (such as subject involvement in the scenario) were introduced, salience effects would not emerge. The rationale for this prediction was that heightened involvement in the scenario would increase attention to relevant cues, thereby reducing the impact of otherwise salient but trivial stimuli. Two studies tested this hypothesis and found that under conditions of involvement with the issue, more engrossing conversations, and a cognitive tuning set to transmit rather than receive, salience effects continued to emerge.

The results of these studies suggest that salience effects have at least some degree of external generalizability. In addition to the conditions of generalizability tested in the present studies (involvement, tuning, distraction, and delay), the results of two pilot studies also extend the domain of applicability of salience effects. In a pilot study by Gartrell (Note 2), salience effects were obtained even when one actor clearly dominated the other in a conversation. In a second pilot study (Taylor & Winkler, Note 3) assessing the impact of arousal on salience effects, power analyses indicated that salience effects would emerge under conditions of arousal but that their magnitude would not be substantially altered by level of arousal. Taking all this information together, we conclude that salience effects do generalize to more engrossing and involving situations than those examined in earlier studies and that salience effects are not dependent on either subject set (transmitting versus receiving) or on immediate assessment of subjects' impressions. The fact that salience effects continue to emerge in interesting, involving, and arousing conditions also makes more plausible the argument that salience may mediate consequential social perceptions.

The results of the present study are also highly suggestive regarding how salience effects themselves are mediated. Elimination of verbal recall leaves the effect untouched (Experiment 1), whereas wandering visual attention may be responsible for the failure to replicate in Experiment 2. The obvious conclusion to draw is that salience effects may well be visually mediated. However, results of an effort to model the mediation process (Fiske, Kenny, & Taylor, Note 4) do not unequivocally support this contention, though the indicators of both verbal and visual recall in those two studies are by no means infallible. In any case, given inconclusive data, we prefer to hedge on the issue of mediation for the present.

The present studies indicate that salience effects are not pushed around very much by the social variables that would be expected to interact with them. Nor are salience effects a function of the subject's set or of the juxtaposition of the salience scenario and the rating task. Indeed, what is striking about the point–of–view effect is that it is quite reliable and practically unmovable. What is suggested to us by this fact is that although the effect is manifested on variables of social interest such as causality or prominence ratings, the effect itself may be an automatic perceptual bias (not unlike optical illusions, orienting to novel stimuli, and the principles of figural emphasis uncovered by Gestalt psychologists). Thus, we would argue that salience effects are automatic responses to stimulus qualities, which the perceiver has never learned and which occur without intention (cf. Schneider & Shiffrin, 1977).

Interpersonal Consequences of Person Perception Processes in Two Social Contexts

Lawrence A. Messé and Gary E. Stollak
Michigan State University

Rita W. Larson
Menlo Park, California

Gerald Y. Michaels
University of Michigan (Ann Arbor)

This research examined the proposition that perceiver-based perceptual processes affect social behavior. Approximately 1,100 undergraduates were exposed to a videotape that portrayed a male or female child interacting with an adult in a playroom. In Study 1, subjects who "saw" the child emit (a) primarily positive behaviors (i.e., subjects who were positively biased), (b) about equal numbers of positive and negative behaviors (i.e., subjects who were accurate), or (c) primarily negative behaviors (i.e., subjects who were negatively biased) then engaged in cooperative task activities with a 7-year-old child. In Study 2, a subset of these subjects engaged in a discussion with another undergraduate about three issues on which they apparently disagreed. Systematic analyses of these interactions suggested that perceptual processes affected social behavior; for example, negatively biased subjects tended to act in a more authoritarian manner in their encounters with the child, whereas positively biased subjects were the least effective in the discussion task. These and the other findings are discussed in terms of their implications for understanding the relationship between person perception and overt social behavior.

There is a set of theories in psychology (e.g., Combs & Snygg, 1959; Kelly, 1955; Rogers, 1959) and sociology (e.g., Cottrell, 1966; Mead, 1934) that explains human behavior in part in terms of person perception processes. For example, Kelly (1969) postulates that how a person "anticipates" events —including interpersonal encounters— through cognitive and perceptual processes affects the course of those events. Similarly, perhaps even more strongly, Combs and Snygg (1959) argue that all human behavior is determined by perceptual mechanisms and processes. This position is also similar to the proposition of role theory (Cottrell, 1966) and symbolic interactionism (Mead, 1934) that people's "definitions of the situation" have a large influence on the course of their interpersonal encounters.

Given that person perception processes are seen by such theorists as important determinants of social behavior, it is somewhat surprising that few studies have attempted to establish empirically the link between perception and behavior (cf. Hastorf, Schneider, & Polefka, 1970; Shrauger & Altrocchi, 1964; Taguiri, 1969). Notable exceptions to this

This article is a revision of two papers presented as part of a symposium held at the 1977 annual meeting of the American Psychological Association. The research reported here as Study 2 was part of the third author's doctoral dissertation, conducted under the supervision of the first two authors, which she submitted to the Department of Psychology, Michigan State University. This research was supported by National Institute of Mental Health Grant MH24250, "Adult Perceptions and Child Behavior Dysfunctions." We wish to thank Linda Giacomo for her help and support, especially during the early stages of this research, and Roger Buldain for assisting with the statistical analyses. We also wish to thank the numerous undergraduates who provided invaluable assistance in collecting and scoring the data. The cooperation of the staff and administration of the East Lansing, Michigan, school district, especially Robert Docking, Malcolm Katz, and Dallas Wegener, is also gratefully acknowledged. Finally, we wish to express our gratitude to the 170 or so children who served as the actors and participants for this research.

Requests for reprints should be sent to Lawrence A. Messé, Department of Psychology, Michigan State University, East Lansing, Michigan 48824.

statement are the seminal work of Kelley (1950) on the consequences of a set to see another as warm or cold, the research on people's reactions to attractive or "stigmatized" others (e.g., Kleck, Ono, & Hastorf, 1966; Snyder, Tanke, & Berscheid, 1977), and—although not usually thought of in this perspective—studies of race effects on interpersonal encounters (e.g., Harrison, Messé, & Stollak, 1971).

While studies such as Kelley's demonstrate that in general, person perception mechanisms play a role in people's overt social behavior, they do not establish the link between such behavior and an important class of person perception variables: those factors in the perceiver (e.g., personality, cognitive structure, etc.) that affect his or her impressions and judgments (Kaplan, 1976; Shrauger & Altrocchi, 1964). Perceptual set, as it was induced by Kelley, is a situational variable, whereas physical appearance variables are primarily factors in the target person. Thus, the relationship between perceiver-based person perception variables and social behavior has not yet been clearly established.

The present research was an attempt to establish the link between social behavior and one perceiver-based person perception variable: the differential attention that persons pay to the behavior of others, especially children. Obviously, children emit a large number of cues or behaviors. Adults who observe them often evaluate these behaviors as "good" (acceptable, desirable, valuable, etc.) or "bad" (unacceptable, undesirable, immoral, etc.). We speculated that some people might be more attuned than others to the "bad" behaviors that children emit, and/or they might be more likely to interpret children's ambiguous behavior as bad; such people could be called negatively biased. Others might be more sensitive to children's good behaviors and/or be more likely to interpret behavior as good; these people would be positively biased. Still others might be more "balanced," that is, not be differentially sensitive to good or bad behavior and/or primed to interpret ambiguous behavior one way or the other. This speculation about "interpersonal perceptual styles" (IPS) is similar to the position of Kaplan (1976) that persons can have general response dispositions that influence their judgments of others.

In the present research, we explored the hypothesized link between IPS and interpersonal behavior in two social contexts: In Study 1, we examined the relationship between IPS and the behaviors that occurred during a cooperative encounter between an adult and a child; in Study 2, we explored the relationship between IPS and behavior within the context of a less cooperative interaction, a discussion between two adults of issues about which they disagreed.

Study 1

We measured IPS by examining people's perceptions of the same stimulus event—videotape excerpts from what was supposed to be a relatively long-term encounter between an adult and a child. We then observed encounters between children and people who, through their responses to the common stimulus event, were identified as negatively biased, positively biased, or perceptually accurate. Given the rather short-term and cooperative nature of this encounter, we expected (a) that IPS would relate more strongly to the behavior of the perceiver (i.e., the adult) than to the behavior of the child with whom she or he interacted and (b) that the behavior of negatively biased persons would differ (i.e., be more controlling and dominant) from that of positively biased and accurate persons, who, in turn, would not differ much from each other.

Method

Subject Recruitment and Selection

An advertisement was placed in the student newspaper of Michigan State University that solicited for persons who were interested in participating in "behavioral research" for pay. Interested persons were instructed to come to a 45-minute interview (dates, times, and place were listed in the advertisement) for which they would be paid $1. The advertisement also stated that those persons who were chosen to participate further in the project could earn $5 per hour for 1 to 3 hours of their time.

Table 1
Mean IPS Scores and Cell Frequencies

Sex of subject	Sex of child in videotape	Subject's IPS category: Positive Score	Positive *n*	Accurate Score	Accurate *n*	Negative Score	Negative *n*
F	F	6.80	14	−.24	13	−16.20	11
	M	7.02	12	−.07	10	−16.38	13
M	F	9.52	12	.07	12	−18.19	12
	M	9.07	14	.81	13	−16.30	11

Note. IPS = interpersonal perceptual style. An IPS score is the difference between the numbers (out of 25 each) of positive and negative behaviors that a subject reported perceiving the target child emit.

About 1,100 persons responded to the advertisement and came for the interview. These sessions were arranged so that potential subjects were examined in groups of 18–25 persons. Each person first completed a brief information sheet that asked his or her name, address, and telephone number, as well as the days and hours during the week that the respondent typically would be available to participate in the study. Then the group was shown the videotaped excerpts of the adult–child playroom encounters, under the guise that the project was concerned mainly with how various groups of people—professional psychologists, older adults, undergraduates, and so on—evaluated the activity of a "graduate student in training." After viewing the tape, the members of the group individually filled out a behavior checklist about the children in the videotape, supposedly so that the interpersonal context of the graduate student's evaluation could be assessed; then they completed instruments that were designed to tap their judgments about the graduate student.

The child behavior checklist was scored by subtracting the number of "negative" child behaviors that a respondent saw from the number of "positive" behaviors that she or he saw; such scores could range from +25 to −25, since the checklist contained 25 behaviors of each type (see below). There were 1,068 scorable checklists. From these, potential subjects were selected for the adult–child encounters such that there were 30 persons of each sex (plus any additional persons, if any, whose IPS score equaled that of the 30th potential subject selected) who best matched the definitions of positive bias, balance, and negative bias. These potential subjects met the following criteria: (a) They checked at least 20 behaviors in all; (b) they were identified as negatively biased if they checked at least 14 more negative behaviors than positive behaviors; (c) they were identified as accurate if the number of negative and positive behaviors that they checked did not differ by more than one; (d) they were identified as positively biased if they checked at least 5 more positive behaviors than negative behaviors.[1] Table 1 presents the mean IPS score and the number of each type of respondents who were selected to participate further.

Children Participants

Through the cooperation of the administration of the East Lansing, Michigan, school district, the parents of all children in second-grade classes were contacted via letter and asked if they would permit their child to volunteer (for $5) to play with an undergraduate in a playroom that was located at the Department of Psychology, Michigan State University. Parents who were interested returned a postcard to that effect, and a sample of these parents was contacted via telephone. In this conversation, the nature of the child's participation was explained in detail, and if the parent agreed, an appointment was made to have the child come to the playroom for the encounter with the undergraduate. In this way, the cooperation and participation of 168 7-year-old children were obtained.

Instruments and Materials

Standard perceptual stimulus (SPS). A script was constructed in which a "graduate student in training"—the word *clinician* was not used to avoid the possibility that the term would induce a negative set in subjects—acted rather passively in a series of encounters with a child. The child was identified as one of several volunteers who were paid to participate with the student. During these encounters, the child, while engaging in a variety of

[1] The criteria used to identify negatively and positively biased respondents differed substantially. This difference occurred because relatively few respondents (less than 2%) checked at least 14 more positive behaviors than negative behaviors, so that, of necessity, the identification criterion for positive bias had to be lowered.

activities, emitted a number of behaviors; some of these behaviors could be construed as negative (e.g., cheating at a game), some could be "seen" as positive (e.g., sharing food with the adult), and some could be perceived as neutral or ambiguous (e.g., painting with watercolors). An attempt was made to portray approximately equal numbers of positive and negative behaviors.

Two female and two male child actors (who ranged in age from 9 to 11 years old) learned the script and were videotaped while they played this role with a female graduate student. The SPSs of the female and male actors who were judged to do the best, most natural jobs were used to determine the perceptual styles of the undergraduates, as described above. About half the respondents saw the tape of the female target child, and half saw the tape of the male. Table 1 presents the number of male and female subjects of each perceptual style who were exposed to the male or female target child.

Child Behavior Checklist (CBC). The CBC, which was used to determine the interpersonal perceptual style scores of the respondents, was a modification of an instrument developed by Ferguson (e.g., Ferguson, Partyka, & Lester, 1974). In its present form it presented respondents with 64 "behaviors" (e.g., "Played with toys in a rough way"; "Did what the adult asked her [him] to do") and asked them to check those behaviors that applied to the child in the videotape that they had just viewed. Fourteen of the items were nonscored "fillers"; the remainder consisted of 25 "positive" behaviors and 25 "negative" behaviors that had differentiated parental perceptions of clinic-referred children from parental perceptions of non-clinic-referred children (Ferguson et al., 1974) and that a sample of about 100 undergraduates judged to be clearly positive or negative. As noted above, IPS was determined by subtracting the number of negative behaviors that a respondent checked from the number of positive behaviors that he or she checked.

Evaluation of graduate student in training. Two forms were used to permit respondents to evaluate the graduate student—the reason they were given for asking them to view the SPS. One was a modification of rating scales that were developed by Bessell and Palomares (1970); the other was a checklist composed of 36 trait words taken from Anderson (1968).[2]

Tasks

The adult subjects interacted with the child volunteers in playroom facilities that were located at the Department of Psychology, Michigan State University. Every adult–child pair engaged in three cooperative tasks, each of which lasted for 10 minutes. In the first ("free play"), both participants were told that they could do what they wanted (i.e., play together or separately, read, just sit there, etc.). In the second task, the pair was asked to reproduce to the best of their abilities a rather complicated figure on an "Etch-a-Sketch." In this task the adult had control of only one knob (and, therefore, one direction), and the child controlled the other knob. Their task was to coordinate their activities so that they produced a reasonable facsimile of the sketch. In the third task, the adult was given a list of proverbs (e.g., "Haste makes waste") and told to try to teach the meaning of them (as many as he or she wished) to the child. The interactions were videotaped through one-way mirrors.[3]

Design

This study used a factorial design whose dimensions were 2 (sex of undergraduate) × 2 (sex of target child; here target child refers to both the sex of the child in the SPS and that of the child with whom the subject interacted, since care was taken to insure that these were always the same) × 2 (IPS of the subject: positive, accurate, or negative, as defined above). Fourteen subjects, chosen at random from the 15 or more potential subjects in each condition, were examined in each cell of the design, but because of equipment failure and the other mechanical problems, final cell sizes ranged from 10 to 14 (see Table 1).

Procedure

All phases of the research were conducted by undergraduate assistants, although one of the first two authors was always available in case some difficulty arose. One assistant escorted the child into the playroom, and a few moments later, a second assistant brought the adult into the room, introduced him or her to the child, and then left. The first assistant then instructed the pair concerning the first task, after which she or he left the room and went to the observation room where a third assistant was videotaping the playroom activity. After 10 minutes, the assistant reentered the playroom to instruct the participants concerning the second task, again leaving the room once the instructions had been read.

---

[2] Since these instruments were not used further in this study, they are not described in any detail here. Note, though, that there was a relationship between these measures and the subjects' perceptions of the child in the videotape (mean $r = .21$). These results support Kaplan's (1976) hypothesis that dispositions in person perception tend to be applied in general within a social context. Thus, in the present context (i.e., the videotaped excerpts), the disposition to see the child as negative or positive appeared to generalize somewhat to perceptions of the adult as well.

[3] Of course, the undergraduates, the children, and their parents all were informed of this procedure beforehand, and all gave their informed consent about this (and all other) aspects of their participation in the study.

This same operating procedure was also employed for the third task. After the session was completed, both the undergraduate and the child were paid the specified amounts of money and thanked for their participation.

Coding of the Adult–Child Interactions

Eight undergraduates (who were kept unaware of the nature of the study until they had finished this task) were trained to use a modified circumplex system of classifying social behavior (Freedman, Leary, Ossorio, & Coffey, 1951). While the 16 specific categories of the system were retained, the scoring procedure was changed from rating scales of intensity to frequency counts of the number of social acts (Bales, 1950) emitted that fell within a given category.[4] Each videotape was scored independently by two coders, and the number of tapes that the various coder pairs scored ranged from 3 to 12.

The average interjudge reliability (correlation coefficient across coder pairs) for each circumplex category ranged from .29 (for suspect) to .93 (for hate), with an overall mean of .48. Because of the somewhat erratic interjudge reliabilities and because of large disparities across coders with respect to the total number of acts that were coded per tape, it was thought best to transform the raw data by converting them to z scores—within a coder within a category—and calculating the mean z score per category across each coder pair. In this way, coders who scored more acts would not influence the results unequally, and, as much as possible, random error would be reduced. Moreover, the frequencies with which interactants displayed categories of behaviors differed markedly. Thus, only half of the categories—structure, cooperate, passively question, dominate, helplessness, help, submission, and reassure—accounted for about 95% of the behaviors that were exhibited. Given the infrequency of behavior within the remaining categories, it was thought best not to examine them further.

Results

The dependent measures—the mean z scores within a coder pair for each of the eight most frequently displayed circumplex categories—were subjected to a 2 (sex of subject) × 2 (sex of target child) × 3 (IPS of subject) × 2 (interactant's score, adult's or child's, a within-dyad measure) multivariate analysis of variance (MANOVA).[5]

Effects of IPS

Given the theoretical framework of the present research, we expected that effects of IPS would appear as a function of who (adult or child) was emitting the behavior; that is, we expected IPS to affect the adult's behavior in this relatively brief encounter to a greater extent (and in different ways, if any) than it would the child's behavior. Thus, we expected the analysis of variance to yield a significant multivariate IPS × Interactant interaction. The MANOVA, in fact, indicated that this was the case, $F(16, 248) = 1.53$, $p < .08$.

Subsequent examination of the univariate IPS × Interactant effects revealed that five of the eight dependent measures yielded a significant interaction: dominate, $F(2, 131) = 5.47$, $p < .005$; structure, $F(2, 131) = 2.84$, $p < .075$; help, $F(2, 131) = 2.77$, $p < .075$; cooperate, $F(2, 131) = 2.88$, $p < .075$; and submit, $F(2, 131) = 4.55$, $p < .02$. These effects were analyzed further via tests of simple effects, and where appropriate, individual comparisons (Winer, 1971, p. 384) were performed between the negative and accurate conditions and between the accurate and positive conditions. Table 2 summarizes the results of these analyses by presenting those cell means that generated significant simple main effects for IPS.

The MANOVA also indicated that the Sex of Subject × IPS × Interactant multivariate in-

---

[4] We felt that the circumplex system was a very judgmental task for undergraduates, even in this simpler form. The somewhat erratic interrater reliabilities that were obtained confirmed that there was a need to be concerned about this issue.

[5] There is some controversy concerning the appropriate procedure to use to select α for a multivariate effect, especially when, as in the case of the present research, a number of dependent measures are used to test rather specific hypotheses (see, for example, Bock, 1975, pp. 422–425). The present research used a slight modification of a procedure suggested by Bock (1975, p. 423) in which the overall, multivariate α is a function of the product of increasingly more stringent univariate βs. For both studies, the β for the "first" univariate was set at .9, and each successive β was raised by a multiple of .025 or .015. Thus, given that Study 1 examined eight dependent measures:

$$\alpha_o = 1 - [(.9)\ (.925)\ (.95)\ (.975)\ (.99)\ (.9925)\ (.995)\ (.9975)] = .248.$$

Likewise, for the 16 dependent measures in Study 2, $\alpha_o = .250$.

Table 2
Mean Social Behavior Scores Reflecting Significant Effects Involving IPS

Circumplex category	IPS category of adult: Negative bias	Accurate	Positive bias	F[a]
	Adult's behaviors			
Dominate	.128[b]	−.060	−.088	3.37**
Structure	.168[b]	−.193	.012	3.71**
Help by males	−.111[b]	.068	.227[b]	2.37*
Submit	−.146[b]	.110	.053	2.69*
	Child's behaviors			
Dominate	−.195[b]	.078	.138	3.94**
Help with male adults	−.006[b]	.235	−.125[b]	2.69*

Note. IPS = interpersonal perceptual style. Values are mean z scores (standardized within each coder and averaged over each coder pair) for each circumplex category that was analyzed. Thus, each social behavior score had an overall mean of 0 and a σ equal to 1.
[a] $df = 2, 262$.
[b] Value differs significantly from accurate IPS mean.
* $p < .10$.
** $p < .05$.

teraction was significant, $F(16, 248) = 1.43$, $p < .13$. This effect reflected one significant univariate interaction, for help, $F(2, 131) = 3.17$, $p < .075$, which was examined further by simple effects tests and individual comparisons. These findings are also summarized in Table 2.

As Table 2 indicates, a number of reasonable results emerged from these comparisons. Negatively biased adults tended to display more dominance and less submission than did accurate perceivers; they also engaged in more acts of structuring. Moreover, negatively biased male subjects were less helpful than were their accurate counterparts. When compared to accurate perceivers, positively biased subjects also engaged in more structuring activity, whereas positively biased male adults tended to be more helpful.

Table 3 presents the mean scores for cooperative behaviors displayed as a function of IPS and interactant. While the simple effects analysis of this dependent variable did not reveal any significant effects for IPS within interactants, it did yield an interesting pattern of results when this variable was further examined from the perspective of differences between the interactants within each IPS category. Such a perspective is especially appropriate for cooperative behavior, because this activity can only be effective when it is expressed by both parties. The analysis indicated that children displayed a greater amount of this behavior than did the negatively biased adults with whom they were paired, whereas the reverse occurred when the adults were positively biased. However, the difference between children and adults was not significant when the adults had an accurate IPS. Thus, the dyads composed of a child and a perceptually balanced adult yielded the most even distribution of cooperative activity.

Three other findings relevant to IPS are worthy of note, since they also involve the behavior of children (see Table 2). The analyses revealed that children displayed less dominance toward negatively biased adults than towards accurate adults, and children were more helpful with accurate males than with either negatively biased or positively biased males.

Thus, taken together, these findings support the position that perceiver-based person perception processes are related to interpersonal behavior.

Sex Differences

The analyses also yielded two significant multivariate effects involving the sex of the interactants: the Sex of Subject × Interactant interaction, $F(8, 124) = 3.24$, $p < .005$, and the Sex of Child × Interactant interaction, $F(8, 124) = 2.02$, $p < .05$. While not a focus of this research, the results of the systematic exploration of the underlying significant ($p < .05$) univariate differences are summarized briefly here, in part because they reflect on the validity of the observational data: (a) Male adults emitted more acts of dominance than did females; (b) children displayed more dominance toward female adults; (c) females were more cooperative than males; (d) children were more cooperative with male adults; (e) male subjects were less submissive; (f) children were more submissive to males; and (g) male children displayed more helpful acts than did their female counterparts.

Discussion

The results supported the basic premise that served as the impetus for this research: Social behavior is related to perceiver-based person perception processes. Moreover, the specific findings that did emerge, on the whole, were reasonable.

Negatively biased adults tended to act to constrain the behavior of the child. This result is especially striking, given the social psychology of the observational setting—that is, the interactants were strangers to each other, their tasks were highly cooperative in nature, they knew they were being observed, and they interacted for a relatively brief period of time (30 minutes)—in which both adult and child most likely were "putting their best foot forward." The pattern of social behavior that negatively biased persons exhibited would be expected of those people who have a propensity to focus on children's negative behaviors, since it is likely that persons of this type would feel that they could not trust the child to act "appropriately" without "adequate" supervision.

Table 3
Mean Cooperative Behavior Scores as a Function of IPS and Interactant

Interactant	IPS of adult		
	Negative	Accurate	Positive
Adult	−.047	−.041	.102
Child	.122	−.089	−.048

Note. IPS = interpersonal perceptual style. As in Table 2, values are mean standardized scores—in this case, of the frequencies of cooperative behaviors that interactants displayed. Again, the overall mean was 0, and σ was 1.

On the other hand, positively biased persons, especially males, tended to be more helpful, if also somewhat more structuring. Again, such activity is reasonable in someone who is relatively inattentive to what most people would consider to be negative behavior in children. In this cooperative social context, though, a positive bias probably was congruent with the child's actual behavior in the playroom.

In addition, the behavior of the children to some extent was related to the adult's IPS, but not as much as we had expected. Perhaps the magnitude of the effect of adult IPS on the child's behavior is reasonable, given that this initial encounter between adult and child was brief and known to be transitory. It is interesting to speculate, however, that if IPS continues to affect adult behavior past the initial stage of an interpersonal relationship with a child, it could come to have a substantial impact on the child's behavior as well.

One conclusion that could be derived from the present findings is that a positive perceptual bias promotes positive interpersonal functioning. No doubt this was somewhat the case for the social context that we examined in Study 1—a cooperative, brief encounter with a child. However, it appeared reasonable to explore the possibility that positive bias would be related to less effective behavior in other social contexts—for example, when persons must deal with each other in an encounter that is not entirely cooperative. This possibility was the focus of Study 2.

Study 2

Specifically, in Study 2 the relationship between IPS and interpersonal behavior in a

mildly confrontational dyadic interaction was examined via three separate sets of dependent measures: a poststudy questionnaire, which measured the participants' reactions to their partner; observers' ratings of the subject and of the total interaction; and structural measures of the interaction, which consisted of the times to completion and the types of outcomes that occurred in a revealed differences task. We expected that, as in Study 1, IPS would be related to the social behaviors that occurred in an initial encounter between the perceiver and another person; and, since this encounter required that persons actively defend their opinions to someone whose position was opposed to theirs, we further expected that positively biased interactants would behave the least effectively.

Method

Subjects and Research Assistants

Subjects were 48 male and 48 female undergraduates who previously had participated in Study 1. Eight subjects were randomly chosen from the 10–14 subjects in each condition of that study, and each was paid $5 to participate in Study 2.[6]

Four confederates (two male and two female), four coders (two male and two female), and a male experimenter were selected from undergraduate psychology majors. These assistants were kept unaware of the purpose of the research and the reasons why subjects were selected to participate until all data were collected. They received course credits for participation in the study.

Design

This study used a $2 \times 2 \times 3$ factorial design, with sex of the subject, sex of the confederate, and IPS, respectively, as independent variables. Each cell contained eight dyads (subject and confederate). Subjects were paired with a confederate of the same sex as that of the target child whom they had viewed in the standard perceptual stimulus.

Procedure and Instrumentation

The subjects were observed interacting with a peer (confederate) in a structured situation that consisted of a revealed differences task. After the subject and confederate had completed a 17-item attitude questionnaire, the experimenter selected 3 items (those the subject had responded to with a strong opinion) and instructed the dyad members to *try* and reach an agreement about the items during the next 30 minutes.[7] All confederates were trained such that they could always advocate, in a rational and nonthreatening manner, a position opposite to whatever the subject defended. The procedure used in this study was very similar to the revealed differences technique developed by Strodtbeck (1951).

After completion of the interaction segment of the study, the subject and confederate were asked to fill out a poststudy questionnaire. In the first part, the respondents indicated along a 7-point scale how well each of 36 personality traits described their partner. The endpoints for the 7-point scales were labeled "very" and "not at all." The 18 positive and 18 negative trait scores were averaged to yield a total positive score and a total negative score. The second part of the questionnaire contained five questions. Four items consisted of evaluating the respondent's partner on 7-point dimensions of persuasiveness, likability, ability to win affection and liking from others, and ability to fit in with the respondent's circle of close friends. The remaining item assessed how comfortable the individual felt during the study.

Coding of Peer Interaction

Two coders independently rated the interaction occurring in a session. Each coder rated an equal number of subjects from each condition. Coders viewed the session through a one-way mirror and heard the interaction through headphones. The coders rated the dyad and subject using five 7-point semantic differential scales. The scales consisted of rating the total interaction (positive–negative) and the subject's

---

[6] Note that 2 to 3 weeks elapsed between subjects' participation in the two studies. Note also that subjects never were informed that the two studies were connected in any way, nor were they told why they were selected to participate. They were led to believe, when they originally responded to the advertisement, that a group of researchers who could pay people to participate in their separate studies were pooling their recruitment efforts. Of course, the personnel that subjects saw in each study were entirely different.

[7] Actually, to make training of the confederates a a more reasonable task, only 8 of the 17 issues were ever chosen for discussion: (a) legalization of marijuana use, (b) women's roles, (c) amnesty for war resisters, (d) the future of the family, (e) Ford's pardon of Nixon, (f) the Protestant Ethic, (g) ecology versus progress, and (h) the role of the university. Because of their salience to subjects at the time that the study was conducted, Topics a and e were almost always used, with the remainder used less frequently and more or less equally. Note, however, that there was no relationship between topics chosen for discussion and subjects' sex and IPS.

Table 4
Means of Measures Yielding Significant IPS Effects

Variable	IPS category: Negative bias	Accurate	Positive bias	*F*
Coders' overall rating of dyads containing male subjects[a]	4.93	5.21	3.46[b]	4.87***
Proportion of time spent reaching moderate disagreement with female confederate	.245	.278	.057[b]	3.24**
Coders' rating of friendliness when confederate was female[a]	5.57	5.67	4.55[b]	2.87*
Coders' overall rating of dyads containing female confederates[a]	5.14	4.92	3.55[b]	4.04**
Interactants' rating of each other's persuasibility when confederate was female[a]	4.03	3.70	2.93[b]	3.04**

Note. IPS = interpersonal perceptual style.
[a] Scores for these variables could range from 1 (very negative, unfriendly, etc.) to 7 (very positive, friendly, etc.).

intelligence, comfortableness, friendliness, and nondefensiveness.[8]

Results

The dyad was used as the unit of analysis, with the exception of the four global ratings that the coders made only of the subject. The 16 dependent measures, comprised of the coders' ratings, the structural measures, and the poststudy questionnaire, were subjected to a 2 (sex of subject) × 2 (sex of confederate) × 3 (IPS) multivariate analysis of variance.[9]

The MANOVA revealed two significant multivariate effects involving IPS: the IPS × Sex of Subject interaction, $F(32, 100) = 1.34$, $p < .14$, and the IPS × Sex of Confederate interaction, $F(32, 100) = 1.25$, $p < .21$. These results reflected six significant univariate effects: The IPS × Sex of Subject interaction was significant for the coders' overall rating of the dyads, $F(2, 65) = 5.24$, $p < .01$; the IPS × Sex of Confederate interaction was significant for the proportion of time that dyads spent discussing issues that resulted in moderate disagreement, $F(2, 80) = 4.38$, $p < .02$; for the coders' rating of the subjects' friendliness, $F(2, 65) = 2.47$, $p < .1$; for nondefensiveness, $F(2, 65) = 2.59$, $p < .1$; for overall rating, $F(2, 65) = 3.36$, $p < .05$; and for the interactants' rating of each other's persuasibility, $F(2, 80) = 3.18$, $p < .05$.

Table 4 summarizes the results of univariate simple effects analysis by presenting the rele-

[8] Coders also scored the interactions in a more molecular fashion, using Borgatta's (1963) Behavior Scores System. While these data yielded a number of reasonable differences as a function of IPS, these findings tended to be redundant with, and somewhat less sensitive than, the data derived from the coders' semantic differential ratings. Thus, for reasons of efficiency, the results of the molecular coding are not presented in this report.

[9] Because of mechanical and procedural difficulties, we were unable to obtain coders' ratings for 15 dyads; moreover, assorted data were missing for 4 other dyads as well. Thus, the sample for the MANOVA had to be restricted to the 77 dyads for which there were complete data. However, it was thought best, where possible, to examine univariate effects—when the multivariate effect was significant—from analyses of variance that were performed on the larger sample.

vant means and significant F ratios. As predicted, the data presented in Table 4 suggest that positively biased subjects were the least effective participants in this mildly confrontational social encounter. Coders rated the interactions involving positively biased males the most negatively; likewise, coders were the least positive in their impression of interactions between positively biased subjects and female confederates. They also judged positively biased subjects to be the least friendly toward their female partners. Moreover, this combination of interactants spent the least time coming to moderate disagreement—which probably was the most appropriate outcome, since confederates were programmed to concede points very slowly—and rated each other as the least persuasive.

Sex Effects

The MANOVA also revealed that the multivariate main effect of sex of confederate was significant, $F(16, 50) = 4.24$, $p < .0001$. Examination of the underlying univariate effects revealed that while the coders judged subjects to be more intelligent and comfortable when they interacted with a female confederate, the interactants themselves were much less favorably impressed with each other (i.e., they rated each other as more negative, less likable, less persuasive, and so forth) when the confederate was female.

Discussion

The results from Study 2 replicated those of Study 1, in that, as predicted, IPS was related to overt social behavior. More specifically, in the somewhat confrontational social context of Study 2, positively biased perceivers engaged in the most dysfunctional interaction, especially when paired with a female partner. During the interaction, the female confederates were assertive, confident, and rational, which is contrary to the common stereotype of females as submissive, weak, and emotional. Perhaps the positively biased perceivers had the most difficulty with female confederates because their self-image is firmly grounded on the traditional stereotype of what a male and female should be. Therefore, when the female did not behave according to her traditional role, the positively biased perceivers might have felt the most threatened.

Taken together, the two studies suggest that persons with an accurate IPS exhibit the most adaptive social behavior across social contexts. Persons with a negative IPS were reasonably adept at interacting within a situation that contained an element of conflict (i.e., the revealed differences discussion), but were less able to behave appropriately in a more cooperative setting. Persons with a positive IPS showed the opposite pattern; they did very well when interacting with a child who was on his or her "good behavior," but appeared to be somewhat inept when confronted with a mild social conflict.

Thus, the two studies demonstrate that there is a link between at least one perceiver-based person perception process and social behavior. Clearly, though, further work is needed. The theoretical perspective that served as the basis of this work (e.g., Combs & Snygg, 1959) postulates that perceptual mechanisms like IPS cause social behavior. It also could be, however, that IPS and interpersonal behavior are related in part because they both are manifestations of some other variable (e.g., need for security). This latter interpretation is plausible, and it is likely to be valid to some extent. IPS is likely to be determined by a number of personality variables that also have a direct impact on social behavior. But it is also likely that there is a direct, causal link between person perception and social behavior as well. As with many phenomena in social psychology, it is probably the case that person perception processes like IPS are both concomitant variables with, and causes of, interpersonal behavior. Establishing empirically the precise relationship between IPS, other components of personality, and overt social behavior would be a most difficult task. However, the findings of the present research suggest that the undertaking of this task would be a worthwhile and fruitful endeavor.

Affective States, Expressive Behavior, and Learning in Children

John C. Masters, R. Christopher Barden, and Martin E. Ford
University of Minnesota

Two experiments with children are presented that illustrate the effects of emotional states on learning and validate experimental affect-induction procedures in which individuals dwell upon thoughts of affect-provoking experiences. Positive affective states enhanced learning, and negative states retarded it dramatically. Ratings of children's facial expressions confirmed that positive affect-induction procedures elicited happy expressions, and negative inductions elicited sad ones. Additionally, positive affect inductions enhanced children's apparent interest, involvement, and arousal, and negative inductions decreased them. These measures were related to learning but proved not to be the sole mediators of the impact of affective states on learning. The thoughts children generated for affect induction illustrated their recognition of naturalistic experiences that induce affective states. These results indicate that young children possess the potential for the cognitive self-control of their own affective states, and the effects on learning indicate that even transient mood states may produce lasting changes in behavior.

Experimentally Induced Affective States

Studies of experimentally induced affective states pose a significant contribution to the scientific study of such states and the determining role that emotions may play in shaping other behavior patterns. It has already been clearly demonstrated that induced affective states in children affect patterns of self-gratification (Moore, Underwood, & Rosenhan, 1973; Rosenhan, Underwood, & Moore, 1974), altruism (Harris & Siebel, 1975; Moore, et al., 1973; Rosenhan et al., 1974; Underwood, Froming, & Moore, 1977), and aggression (Harris & Siebel, 1975), and mood states thus seem likely to determine the performance of a broad range of social behaviors, many of which are so far unstudied. There are also compelling arguments for the possibility that affective states may influence the effectiveness of learning processes and may consequently have far-reaching effects on the development of new behavior patterns through social learning or on intellectual functioning in achievement settings.

Consequences of Affective States for Behavior and Learning

Theoretically, the effects of a given affective state may be due to a variety of mediating processes, perhaps different ones, depending upon the behavior pattern being affected. For behaviors such as self-gratification or altruism, it has been proposed that the pleasant or aversive nature of a given state serves as a motivational determinant for behaviors that will maintain the state if it is positive or reverse the state if it is negative (Moore et al., 1973; Rosenhan et al., 1974; Underwood et al., 1977). The influence of affective variables on persistence at effortful behavior may be mediated by reinforcement effects, if the variables are of positive or negative valence, such as favorable or unfavorable self-evaluation

Preliminary versions of this experiment constituted an undergraduate summa cum laude honors thesis by the second-named author. The able assistance of Craig Binger is gratefully acknowledged.

(Masters & Santrock, 1976) and if they are consequent to the effortful behavior. There is some evidence, however, that the impact of self-evaluations and their emotional concomitants may affect learning through incentive or other motivational mechanisms that are not consequent to learning but actually occur in anticipation of intellectual mastery (Masters, Furman, & Barden, 1977). Thus, mood states bearing no contingent relationship to performance may affect performance, learning, or mastery not through reinforcement processes but through motivational or arousal components.

Affective states may also have an indirect effect on behavior and learning—an impact mediated by the actions of others whose behavior towards an individual is influenced by that individual's apparent affective state. There is ample evidence that people's beliefs and biases about the characteristics of others influence their behavior towards these others (Mischel, 1968; Rosenthal, 1966, 1969). Certainly, a child who appears happy or sad, interested, involved, or aroused may elicit different treatment from parents, teachers, peers, or other agents of socialization, and this treatment is then likely to influence behavior and apparent competence in social or intelectual contexts. Facial expressions of emotion are common and socially significant. They are also scientifically significant and have been used successfully to index internal affective states (Ekman, Friesen, & Ellsworth, 1971; Ekman et al., 1972). However, investigations utilizing experimental affect-induction procedures have failed to gather direct validating evidence, such as changes in affective facial expressions. The demonstration of appropriate changes in facial expressions following different affect-induction manipulations would strengthen the assumption that affective states were truly induced, as well as give some indication of changes in a child's social stimulus characteristics as a function of the affect-inducing experience.

Two experiments are presented that examine the effects of positive (happy), neutral, and negative (sad) affective states on children's mastery of a learning problem. In addition to the affective valence, the tempo of a given emotional state was independently manipulated within an induction procedure to establish active or passive forms of the positive, neutral, and negative affective states.[1] Three basic predictions were made: (a) Positive affective states will enhance learning, and negative states will interfere; (b) a tempo component that is active will promote effective learning, and one that is passive will not; and (c) induced active tempo will increase the speed of ongoing learning behavior (average time to solve individual problems). These predictions were based on the following reasoning:

1. Positive states may also enhance the effectiveness of social reinforcers (right–wrong feedback delivered by an experimenter; Byrne & Clore, 1970; Gouaux & Gouaux, 1971; Izard, 1964).

2. Negative affective states will interfere with learning through distraction, by diverting attention away from the task and onto attributes of the self (Mischel, Ebbesen, & Zeiss, 1973) and by failing to induce any incentive for mastery (Masters et al., 1977).

3. Positive affective states may also motivate greater attention to the task plus a striving for success, since success experiences will maintain the affective states (Masters et al., 1977; Mischel et al., 1973; Rosenhan et al., 1974).

4. Induced active tempo will enhance learning accuracy through increased arousal, interest, and involvement in the task, compatible with the long history of research bearing upon the facilitative effects of moderate arousal on learning (e.g., Izard, 1964; Izard, Wehmer, Livsey, & Jennings, 1965; Velten, 1968; Woodworth & Schlosberg, 1954).

Experiment 1 was conducted to evaluate the accuracy of the predictions regarding the effects of affect and tempo on learning. Ex-

[1] It should be noted at this point that the interaction of arousal and valence may produce different labels for affective states (e.g., active–positive might be termed elation; passive–positive could be serenity; active–negative might be agitated depression or anger; passive–negative might be depression, sadness, or grief). Such labels will not be used here, nor were they utilized in the experiments, since the influence of such labeling was not under investigation.

periment 2 replicated Experiment 1 and in addition provided data relevant to hypotheses concerning other consequences of affective states. In this experiment, children's facial expressions were recorded on videotape following the affect and tempo induction procedure; these expressions were rated according to the degrees of various emotions that were apparent and according to expressional indexes of factors related to learning, such as interest, involvement, and arousal (Ekman et al., 1971; Ekman et al., 1972). For purposes of convergent and discriminant validation of the affect-induction procedure, children's facial expressions were rated on convergent dimensions of happiness (positive affective state) and sadness (negative affective state) and on divergent dimensions as well (e.g., fear, disgust, surprise). To provide additional validity evidence, the thoughts that children generated for the affect induction were independently rated for affective tone by a panel of adult raters.

Method

Subjects

For each experiment, 48 4-year-old children served as subjects. Children were drawn from nursery schools in a large metropolitan area. They were equally divided by sex and randomly distributed according to socioeconomic status and racial background. The experimenter was a male adult.

Procedural Overview

For both experiments, children were brought to an experimental room by the experimenter. Then the affect induction commenced and was followed by the learning task. At the end, children were asked to recall the thought that they had generated for the affect induction, and then, if they had been in a negative affect condition, a positive affect induction was included to offset any lingering effects of the negative induction. In Experiment 2, just before and immediately following the learning task, children were asked to sit for a moment, during which time their facial expressions were silently recorded via a video camera standing in the corner of the room.

Experimental Manipulations

There were three levels of affect and two of tempo, resulting in six experimental conditions. The affect-induction procedure was similar to that employed by earlier investigators (Masters & Furman, 1976; Rosenhan et al., 1974) and involved asking the child to generate a thought of the appropriate affect and tempo and to concentrate on it for 30 sec. The child did not communicate the content of his or her thought to the experimenter until the experiment was completed, to minimize any experimenter bias. At that time, a record was made of the thought content. The affect and tempo induction was as follows:

> You know, (subject's name), sometimes things happen to us that make us feel happy, and sometimes things happen to us that make us feel sad, and sometimes things happen to us that don't make much difference to us. Can you remember something that happened to you that made you feel:
>
> (positive affect, active tempo) so happy that you just wanted to jump up and down?
> (positive affect, passive tempo) so happy that you just wanted to sit and smile?
> (neutral affect, active tempo) like jumping up and down?
> (neutral affect, passive tempo) just like sitting?
> (negative affect, active tempo) so sad that you wanted to jump up and down?
> (negative affect, passive tempo) so sad that you just wanted to sit and frown?
>
> Now (subject's name), I want you to use your imagination, all right? Our imagination really works sometimes, doesn't it? It can really make us believe things, can't it? All right now, (subject's name), just look at my light box (the learning equipmment) and really use your imagination for a few seconds and think of something that makes you feel (same as above). That's right, think of something that makes you feel (same as above).

The child was then given 30 sec to stare at a plain gray box and think.

Learning Task

Following the affect/tempo induction procedure, children were introduced to the learning task, one involving shape discrimination (Masters et al., 1977). There were 12 individual discrimination problems making up a trial block, and a "tower of lights" indicated a child's performance by illuminating a series of lights, one for each problem solved correctly by the child. Children were given up to 10 trial blocks to achieve perfect mastery of the 12 problems, and an additional trial block was run for those children whose performance was less than perfect on the 10th trial, in order to make certain that the right–wrong feedback during that trial had not allowed them finally to achieve mastery. There were three stimuli in each problem, one of which was designated correct, and their order in a horizontal array was varied for each presentation of the problem. The measures of rate and accuracy of learning utilized for purposes of analysis were the amount of time taken to reach perfect mastery, the number of trials to perfect

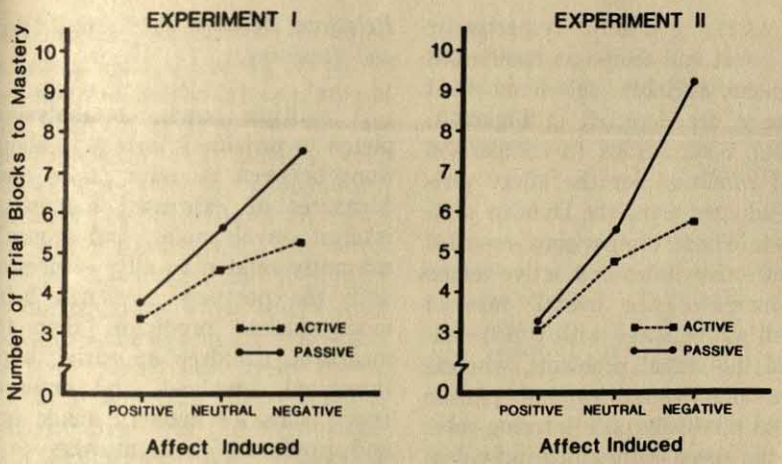

Figure 1. Mean number of trial blocks (maximum = 10) to perfect mastery for both experiments as a function of affective valence and active or passive tempo.

mastery, the total number of errors, and the mean amount of time spent considering individual problem solutions.

Independent Measures of Expressed Affect

In Experiment 2, children's facial expressions were videotaped for a 30-sec period at two times during the experimental session. The first recording occurred immediately following the affect-induction period and just prior to the learning task (pretask), providing an index of the impact of the induction procedure and allowing the assessment of affect, attention, and arousal measures that might be predictive of learning performance. The second recording occurred immediately upon the completion of the learning task (posttask) and tapped the continued impact of the induction procedures as they had persisted throughout the learning task, plus any effects generated by the learning experience itself.

Facial expression ratings were completed according to the categories defined by Ekman (Ekman et al., 1971). The following categories were utilized: happiness, sadness, pleasantness, interest, involvement, arousal, disgust, fear, pain, and surprise. Two raters independently viewed the videotaped segments without knowledge of the nature of the experiment or the hypotheses involved. They were alerted to consider the duration of a facial expression, its relative intensity, and the frequency of its occurrence during the 30-sec period, in order to judge the intensity (Ekman et al., 1972). All ratings were on a 9-point scale, with 1 equated to the absence of a particular state but not the presence of its opposite (e.g., 1–happiness did not imply any degree of sadness). Rater reliability was assessed for all subjects in terms of percentage of agreement between the raters and ranged from .80 to 1.00 across all dimensions (median agreement = 94%).

Thoughts Utilized in Affect and Tempo Inductions

The thoughts that children generated on the affect induction in Experiment 2 were submitted to five adult judges who rated them on both affective tone and tempo. After the initial ratings were completed, the raters were informed of the experimental manipulations and were allowed to read the experimental instructions for all conditions. They were then asked to review the thoughts once more and estimate (a) which affect induction the child had experienced and (b) which tempo induction the child had experienced. Average interrater agreement across all five raters ranged from .65 to .92, with a median value of .73.

Results

Effects of Induced Affective States on Speed and Accuracy of Learning

The four learning measures (total time to mastery, number of trials to mastery, total number of errors, and mean amount of time spent on each problem) were significantly intercorrelated; consequently, a single multivariate analysis of variance was performed. The results were identical for the two experiments, and since Experiment 2 also contained the measures of affective expression, only the statistical results of Experiment 2 are specifically reported.

The multivariate analysis revealed significant main effects due to both affect and tempo, $F(8, 144) = 53.59$, $p < .001$, and

$F(4, 144) = 43.11$, $p < .001$, respectively. The effects of affect and tempo as manifested on one dependent variable, the number of trials to mastery, are depicted in Figure 1. Individual group comparisons (a comparison to the neutral condition for the affect variables) were conducted using the Duncan multiple-range rest. These comparisons revealed that positive affective states and active tempo significantly increased the overall rate of learning as well as the speed with which children processed individual problems, whereas both negative affective states and passive tempo produced relatively poor learning rates and retarded the speed with which individual problems were processed.

The interaction between affect and tempo also proved significant, $F(8, 144) = 12.11$, $p < .001$. In general, the difference between active and passive tempo was enhanced for the negative affect condition, although this was less true for the mean time spent on each problem than it was for the other learning measures. This interaction, which can be seen particularly well in Figure 1 with respect to one learning variable, may be due to a partial ceiling effect for the positive affect conditions, in which children often learned in as few trial blocks as possible, many showing perfect mastery after only the second block of learning trials (accuracy on the first trial block was chance, since correct solutions were not given in advance).

It is of interest to note here the contrast between the different effects of affective states on the overall number of trials to task mastery and the speed with which children produced solutions for individual problems. Those affect and tempo conditions that promoted fewer errors and rapid overall mastery in fewer trials also increased the speed with which children solved individual problems. Under conditions of various affect and tempo inductions, the "impulsive," rapid answer was more likely to be correct, and the slower, "reflective" response incorrect. The correlation between number of trials to mastery and mean time per problem was $r(48) = .47$, $p < .01$.

Relations Between Expressed Affect and Learning

A multiple regression analysis was completed to provide information about the relations between affective states and learning. Measures of expressed happiness, sadness, interest, involvement, and arousal were significantly related to all measures of learning, with the posttask measures being slightly more efficient predictors than the pretask measures. Children appearing happier, more interested, involved, and aroused required fewer trials for mastery, made fewer errors, and produced their answers to individual problems more rapidly. Children appearing sadder and not particularly interested, involved, or aroused required more trials, made more errors, and spent longer on the solution of individual problems.

Since the measures of expressed affect and of interest, involvement, and arousal were quite highly correlated with one another, median $r(48) = .51$, further multiple regression analyses were undertaken to determine the degree to which expressed affect and interest/arousal variables contributed to the variance in learning. The multiple correlations between the prediction set and two measures of overall rate and accuracy of learning were .72 and .64 ($df = 6, 41$, $p < .01$) for trials to mastery and number of errors, respectively. Significance tests for individual beta weights revealed that expressed happiness and sadness were the most powerful predictors of the rate and accuracy of overall learning, and expressions of apparent task involvement or arousal contributed little. The multiple correlation using affect and interest/arousal variables to predict processing speed for individual problems was $R(6, 41) = .51$, $p < .05$. Only expressed sadness had a significant beta weight in the predictor equation for the amount of time spent on individual problems—a result that interestingly parallels the clinical picture of depression as one of psychomotor retardation.

To test further the implication that expressed pretask and posttask interest, involvement, and arousal were less powerfully related to learning than affect, a stepwise multiple regression analysis was performed,

this time entering the predictors in the equation in two orders. First the affect predictors were entered, followed by the interest/arousal variables, and then the reverse. For the rate and accuracy of overall task mastery, each set of variables accounted for a significant amount of variance, but the magnitude of the contributions was very different. The affect measures added between 20% and 30% more variance to the equation when added after the interest/involvement/arousal variables, whereas the latter added only from 1% to 3% more variance when the affect measures had been included first (but this slight addition was still significant). With respect to the amount of time children spent on individual problems, the stepwise regression analysis revealed that the interest/involvement/arousal variables did not contribute significantly to the predictor equation.

These results indicate that positive and negative expressed affective states are strongly associated with the overall rate and accuracy of children's learning, and negative states influence the speed of cognitive processing, or at least the rapidity with which a solution is reported. Apparent interest, involvement, and arousal are also related significantly to learning, but the relation is modest at best, and it does not appear that these variables are major mediating factors in the relation between affective states and learning.

Convergent and Discriminant Validation of Affect-Induction Procedures

Facial expression ratings. In order to assess the convergent and discriminant validity of the affect-induction procedures, analyses were conducted to determine the effects of the various experimental conditions on pretask ratings of affective states from the facial expression data. Two types of convergence and discrimination were examined: (a) the degree to which affect-induction manipulations influenced appropriate facial expression ratings and tempo-induction manipulations did not and (b) the degree to which the affect-induction procedures influenced the appropriate affect ratings (pleasantness, happiness, sadness) in an understandable fashion and did not influence ratings of divergent affective states (anger, disgust, surprise, pain).

Table 1
Mean Degree of Expressed Affect Following Positive, Neutral, and Negative Affect Inductions

Affect induction	Affective expression rating[a]	
	Happiness	Sadness
Positive	6.76	1.03
Neutral	3.91	1.44
Negative	2.91	3.04

Note. $n = 16$ for each mean.
[a] Maximum = 9.00; minimum = 1.00.

Analyses of the effects of sex, affect induction, and tempo induction on pretask ratings of happiness and sadness revealed significant effects only for affect induction (happiness: $F(2, 36) = 24.99$, $p < .01$; sadness: $F(2, 36) = 5.44$, $p < .01$. Means are presented in Table 1, and they reveal clearly that the effects were appropriate for the different induction conditions. Individual group comparisons indicated that for happiness, the positive affect condition differed significantly from both the neutral and negative conditions. For sadness, the negative affect condition differed significantly from the neutral and positive conditions, and the positive condition differed from the neutral condition as well. Figure 2 illustrates the facial expressions of four children, two following the induction of a positive state and two following the induction of a negative state.

Discriminant validity was revealed by an examination of the effects of the affect-induction procedures on the ratings of divergent emotional states. There were no significant effects whatsoever from the affect-induction procedures on ratings of anger, disgust, surprise, or pain. A significant main effect of induced affect was observed for ratings of fear, $F(2, 36) = 5.01$, $p < .05$. These ratings were all quite low, and children in the neutral condition were rated as showing somewhat more fear ($M = 2.16$) than children in either the positive ($M = 1.07$) or negative ($M = 1.25$) affect conditions. This finding

Figure 2. Facial expressions, photographed from videotape, of four children participating in Experiment 2—two from the positive affect-induction conditions and two from the negative affect-induction conditions.

may indicate simply a mild degree of apprehension in children after the difficult assignment of determining a neither happy nor sad experience to dwell upon, with no feedback given regarding their success.

Analyses of affect- and tempo-inducing thoughts. The thoughts generated by children were rated for their degree of intrinsic happiness, sadness, activity, or passivity. These ratings were analyzed to determine the degree to which the experimental conditions of affect and tempo induction inclined young children to generate thoughts that were identifiable by adults as matching the intended affect or tempo manipulation. The ratings were submitted to two-way analyses of variance with primary dimensions of affect and tempo induction. The means for all analyses are presented in Table 2.

The analysis of happiness ratings revealed a significant main effect for the affect induction, $F(2, 23) = 22.67$, $p < .01$. The thoughts produced by children to effect the positive affect induction were rated significantly more happy than those produced by children in the neutral condition, who in turn produced thoughts judged happier than those from children in the sad condition. Analysis of sad ratings also revealed a significant main effect of affect induction, $Fs(2, 23) = 21.20$, $p < .01$. The thoughts produced by children in the sad condition were rated more sad than those from children in the neutral condition, who in turn produced thoughts rated more sad than those from children in the happy condition.

Analysis of the activity and passivity ratings revealed main effects of tempo, $Fs(1, 139) = 5.82$ and 6.51, $p < .01$, for activity and passivity, respectively, and a significant interaction between activation and affect induction, $Fs(2, 23) = 8.47$ and 7.46, $p < .01$. Thoughts from children in the active tempo conditions were rated significantly more active

Table 2
Mean Ratings of the Happiness, Sadness, Activity, and Passivity of Children's Self-Generated Thoughts as a Function of Affect and Tempo Inductions

Rating dimension	Tempo induction	Affect induction: Positive (n = 16)	Neutral (n = 16)	Negative (n = 16)
Happiness	Active	7.95	5.35	2.16
	Passive	7.07	4.05	1.93
Sadness	Active	1.25	2.60	6.72
	Passive	1.23	2.60	6.43
Activity	Active	5.85	7.05	3.60
	Passive	4.50	2.70	5.10
Passivity	Active	2.70	2.20	5.12
	Passive	4.07	6.30	3.93

than those from children in the passive conditions, and the reverse was true for the passivity ratings. However, these findings were qualified by the interactions. Thoughts from children in the neutral condition were clearly recognizable as being from either the active or passive activation induction according to both rating dimensions. However, this distinction was greatly reduced for thoughts from children in the positive affect condition. Furthermore, the thoughts generated by children in the negative affect condition were commonly *mis*judged by raters. There was a tendency to judge thoughts from the passive–sad condition to be more active than those from the active–sad condition, and vice versa for the passive ratings. These results indicate that the presence of a clear affective tone, especially a negative one, tends either to confuse children in their generation of active or passive scenes or to produce thoughts that are active or passive to them but not to adult raters judging those thoughts. The latter seems to be the more likely explanation, since the experimental results revealed effects of tempo on learning, without any significant reversals as a function of the affect induced.

Discussion

Role of Affect in Social Learning

The finding that affect strongly influences learning enhances our understanding of the role that affective variables may play in development. Mood states may be transient, but if they influence adaptive learning, their consequences may be widespread and of long duration. The current affective state of an individual in any context is an important person variable that is likely to mediate any influence of cognitive or contextual learning variables and may well constrain or amplify the possibility for prior experience and learning to mold adaptive behavior. The present findings also indicate that the impact of emotional states should not be underestimated. The affective states induced in this experiment were surely less varied than the states induced by uncontrollable experiences children have in the natural environment. Most of the thoughts generated by children represented social experience with parents, teachers, or peers, and the thoughts must surely have induced weaker affective states than did the original experiences.

The implications of the present findings extend beyond the academic or intellectual context. Although the present experiment utilized an intellectual learning task, there seems little reason to believe that affective states will not also affect children's social learning in nonintellectual contexts. Thus, children's sensitivity to social reinforcement or punishment or to the behavior of peer or adult models may depend at least in part upon the children's ongoing affective state. The effectiveness of social learning variables, punishment for instance, may also be mediated

by the affective states that are induced by the social learning variable itself during the learning interaction. The role of affect as a participant or mediating variable in intellectual or social learning simply has not yet been explored.

The fact that children's self-generated thoughts can create intended affective states raises the possibility that children possess at least the potential ability to manipulate their own affective states and possibly intervene in a therapeutic fashion to terminate the persistence of a negative affective state or enhance an existing positive state. There is some evidence to indicate that children may ameliorate unpleasant experiences and affective states by selective exposure to contexts that are likely to induce opposing states or provide desired experiences (Masters, Ford, & Arend, Note 1). The present results indicate that the "power of positive thinking" or a rational–emotive analysis (Ellis, 1962, 1971) is not without application to young children, and cognitive abilities to induce affective states may very early become part of an individual's armamentarium of self-regulatory skills, providing some degree of personal control over mood states and their consequences.

Tempo and Affect

The results of the present two investigations indicate that the tempo component of an affective state may be an important contributor to the effects achieved on a broad range of behaviors. The learning data also revealed that inductions with an active tempo enhanced learning in much the same way that the induction of a positive affective state did. Nevertheless, in many instances three was a significant interaction between activation and affect, illustrating an apparent interdependence of the valence and activation components of specific affective states. Labels exist in the language that appear to be appropriate for different combinations of affect and tempo (e.g., positive/active = elation or joy; positive/passive = serenity, pleasure, or perhaps contentment), and the present findings indicate that a conceptual dissection of emotional states into hypothesized dimensions beyond merely that of affective valence is a heuristic procedure for future research.

Children's Comprehension of Affect and Affect-Inducing Experiences

Little is known about children's concepts of affect, but the present results indicate that even those of preschool children correspond quite well to those of adults. Preschool-age children's comprehension of the affect that they do feel or are expected to feel in various circumstances is well developed, and they comprehend the determinants of a given affective state well enough to propose appropriate antecedent conditions. In the present experiment, it was difficult to tell which of the thoughts that children generated were recollections of their own past experiences and which were more normative nominations of experiences anyone might have that would produce the affective state in question. Some thoughts were of everyday experiences: sitting and watching TV (neutral), helping to clean up the house (negative), jumping on one foot (neutral), or going on a vacation to Chicago (positive). Others, however, appeared to be concocted rather than recalled, such as having a turtle throw a shell at one (negative) or when Santa comes and leaves no present (negative). The response of at least one child indicated an awareness of vicarious experiences that may produce an affective state: watching a friend on a bike make a funny jump (positive). Very young children thus appear to have the ability to identify affect-inducing experiences and a comprehensive understanding of culturally defined affect labels. The dimensions of these skills and knowledge are at present only poorly understood.

The diversity of content spontaneously utilized by children in generating the affect-inducing thoughts also suggests the need for further investigation into the classes of experiences that may generate affective states. Just as the effects of success or failure on levels of aspiration are constrained by the contextual character of that experience, so that, for example, academic failure will not necessarily lower aspirations for athletic accomplishments, the contextual nature of af-

affect-inducing experience may focus the impact of the induced state upon relevant or related subsequent behaviors. For example, in the present experiments, some children generated thoughts that were distinctly social in nature (dad helping me jump up and down; when grandma visits; when my father spanked me), whereas others thought about contexts that were private (candy; sitting and watching TV; breaking toys accidentally). A private–social dimension such as this may be relatively unimportant for a private activity like learning but be influential in determining subsequent social behavior such as altruism. Similarly, some children generated thoughts about experiences with intrinsic social comparison components (everybody's eating candy but me), whereas others nominated contexts that contained peers, but without any comparative overtones (when my friend comes over and then leaves in a huff; when a friend calls me a copycat). In short, the effects of affective states on various social and intellectual behaviors may be discriminated according to aspects of the precipitating experiences other than simply the affective valence.

Factors Mediating the Behavioral Consequences of Affective States

The factors mediating the effects of affective states on behavior have rarely been explored. In the present instance, expressive indicators of both pretask and posttask interest, involvement, and arousal very clearly were influenced by induced affective states and were related to children's learning. However, careful analysis revealed that interest/arousal factors were related to learning in a manner independent of the affective factors, and they were clearly not a prime mediator for the effects of affective states on learning. The mediating role of attentional and arousal factors cannot be ruled out, because of the possibility that facial expressions are not the best indicators of ongoing attentional behavior during learning. There is growing evidence, however, that changes in attentional behavior are not a major consequence of affective states. Underwood et al. (1977) have already shown that measures of incidental attention are unaffected by induced affective states. More recently, Isen, Shalker, Clark, and Karp (1978) found that positive affective states affected the recall of positive memories, which suggests that the impact of affective states on learning may occur during retrieval or recall performance rather than during attentional or encoding phases.

Validation of Experimental Affect-Induction Procedure

The inclusion of independent assessments of affective states provided clear convergent and discriminant validity for the experimental affect-induction procedure. The availability of techniques to manipulate emotional states under controlled conditions and in normal individuals is an important methodological advance, and there should be further attempts to demonstrate the validity of this manipulation through the use of independent indexes of induced affective states. In the present case, the use of expressed affect and interest/arousal indexes also provides information about another aspect of emotional states, the degree to which they may alter the social stimulus characteristics of the person experiencing them. Among the factors mediating the effects of emotional or mood states on behavior are the social reactions of others, reactions which may in part be determined by the appearance of the person experiencing the affective state. The present results indicate that expressional changes during affect may involve aspects or judgments of appearance other than those given affective labels per se. Thus, for example, the impact of affective states on learning in the intellectual context may be shaped by a teacher's judgments of a pupil's interest or involvement rather than by judgments of an ongoing mood state. The external, social consequences of internal and presumably private states merit direct investigation.

Conclusion

In summary, the role that affective states may play in intellectual and social behavior is becoming ever more documented. The pre-

sent results indicate that the experimental procedure of inducing affective states is valid and effective and can provide an important investigative tool in exploring the role that affective states may play in shaping cognitive and social aspects of both the normal and disordered behavior of children and adults. Further descriptive investigations are certainly in order, providing both examples of the social and private experiences that are likely to induce affective states and examples of the range of behaviors and capabilities that are sensitive to affective determinants. Also of importance is the further investigation of the nature of affective states, including the elucidation of companion factors, such as tempo, that influence the impact of affective states and the cognitive, attentional, and social mechanisms that mediate observed effects on learning and behavior.

Stimulus Recognition May Mediate Exposure Effects

Michael H. Birnbaum and Barbara A. Mellers
University of Illinois at Urbana-Champaign

Moreland and Zajonc presented stimuli with differential numbers of exposures to subjects and obtained measures of affect (e.g., ratings of liking) and ratings of familiarity. Exposure frequency and ratings of familiarity were both significant predictors of affect in a multiple regression equation. Moreland and Zajonc concluded that there are two independent effects, and thus the exposure effect could not be explained by a stimulus recognition factor alone. However, these results can be explained by the theory that exposure frequency affects a single mediator that is imperfectly correlated with ratings of familiarity and affect. Thus, the null hypothesis that recognition mediates the exposure effect cannot be refuted by the partial correlation and regression analyses of Moreland and Zajonc.

Moreland and Zajonc (1977) varied the frequency with which stimuli were presented and obtained several dependent variables including ratings of familiarity and a measure of liking (affect). Since the rating of affect could be predicted from rated familiarity and exposure frequency and since both regression coefficients were significant, it was argued that there are two "independent" effects. However, the present article shows that the theory that one factor, subjective recognition, mediates the effect of the independent variable on both dependent variables can predict this outcome.

Single-Mediator Theory

Suppose the manipulated variable, exposure frequency, affects a mediator, subjective recognition,

$$S = g(A^*) + s, \tag{1}$$

where S is subjective recognition, A^* is actual exposure frequency, s is a random residual, and g is some function (e.g., logarithmic) of actual frequency.

Suppose that ratings of liking (L) and ratings of familiarity (R) are correlated with subjective recognition,

$$L = aS + l, \tag{2}$$

and

$$R = bS + r, \tag{3}$$

where a and b are linear constants, and l and r are residuals that are uncorrelated with S, s, or each other.

It follows that the intercorrelation between each pair of variables can be expressed as the product of the correlations between the two variables and the mediating factor, subjective recognition:

$$\rho_{ij} = f_i f_j, \quad i \neq j, \tag{4}$$

where ρ_{ij} is the correlation between variables i and j; f_i and f_j are the correlations between the variables and subjective recognition. Since each correlation is the product of the correlations with a mediating factor, S, the path model defined by Equations 1, 2, and 3 is equivalent to a one-factor model.

Interpretation of Partial Correlations in Single-Mediator Theory

The least squares regression coefficient in the (standardized) equation predicting ratings of liking from transformed exposure frequency, $A = g(A^*)$, and rated familiarity is given by

We thank Richard Moreland for providing us with the correlation matrices in Table 1.

Table 1
Correlations of Variables from Moreland and Zajonc (1977)

	1	2	3	4	5
1. Frequency		.42	.64	.53	.41
2. Affect	.66		.40	.35	.25
3. Familiarity	.58	.53		.47	.54
4. Confidence	.34	.25	.29		.48
5. Accuracy	.41	.30	.55	.42	

Note. Correlations above and below diagonal are for Experiments 1 and 2, respectively. Frequency represents log $(f + 1)$, where f is actual exposure frequency. Liking and affect are corresponding dependent variables for Experiments 1 and 2, respectively.

the expression:

$$\beta_{LR\cdot A} = \frac{\rho_{LR} - \rho_{RA}\rho_{AL}}{1 - \rho_{RA}^2}, \quad (5)$$

where $\beta_{LR\cdot A}$ is the beta coefficient for rated familiarity in the equation predicting rated liking with transformed frequency (A) partialed out. (The corresponding partial correlation has the same numerator as Equation 5.)

Substituting Equation 4 into Equation 5 yields

$$\beta_{LR\cdot A} = \frac{f_L f_R(1 - f_A^2)}{1 - f_R^2 f_A^2} = \frac{\rho_{LR}(1 - f_A^2)}{1 - \rho_{RA}^2}, \quad (6)$$

which shows that unless subjective recognition is perfectly correlated with frequency ($f_A^2 = 1$), the beta is expected to be non-zero and to have the same sign as ρ_{LR}.

Similarly, the beta for A in the equation predicting liking will be given by

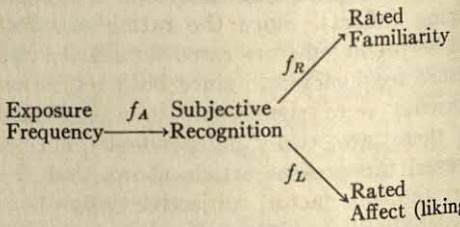
$$\beta_{LA\cdot R} = \frac{\rho_{LA}(1 - f_R^2)}{1 - \rho_{RA}^2}, \quad (7)$$

which shows that the coefficient of frequency is expected to be non-zero and to have the same sign as the correlation between exposure frequency and liking, unless rated familiarity is perfectly correlated with subjective recognition ($f_R^2 = 1$). Thus, the finding of a positive partial correlation between liking and frequency with rated familiarity partialed out is consistent with both the single-mediator (null) hypothesis and the alternative. This partial correlation is therefore not diagnostic of the presence of two independent effects on liking, as contended by Moreland and Zajonc (1977).[1]

One or Two Mediators?

The correlations between exposure frequency, rated familiarity, and affect (liking) for Experiments 1 and 2 of Moreland and Zajonc (1977) are shown in Table 1. The off-diagonal correlations among these three variables can be perfectly fit by the single-mediator model in each case.[2] For Experiment 1, the correlations with the mediator are .82, .78, and .51, respectively; for Experiment 2, the correlations with the recognition mediator are .85, .68, and .78 for frequency, rated familiarity, and affect (liking), respectively.

Consequently, the three correlations are consistent with the representation shown below, in which each correlation among observed variables is the product of their correlations with subject recognition (Equation 4):



. (8)

This model can be extended to describe the intercorrelations among the other dependent variables measuring recognition.

The alternative to Equation 4 is that there is an additional effect of frequency on liking that operates independently of the effect of

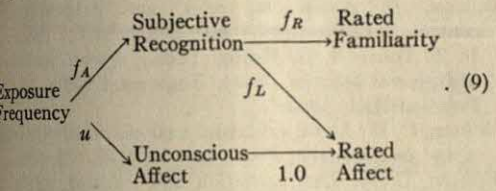
[1] Should a partial correlation have a sign opposite to that of the original correlation (i.e., $\rho_{ij\cdot k}\rho_{ij} < 0$), it would not be consistent with a one-mediator model. Though it may seem counterintuitive, a *negative* partial correlation between exposure frequency and rated familiarity with liking partialed out would have been inconsistent with the single-mediator model, but in agreement with the presence of a second effect of frequency on liking.

[2] For a three-variable, positive intercorrelation matrix, the path coefficients (factor loadings) are given by the following equation:

$$f_i = \sqrt{\frac{\rho_{ij}\rho_{ik}}{\rho_{jk}}},$$

where f_i is the correlation between Variable i and the mediating variable.

frequency on recognition. This theory can be epresented as follows:



. (9)

The single-mediator model (Expression 8, Equation 4) implies that the correlations atisfy the following:

$$\rho_{ij} \leq \frac{\rho_{ik}}{\rho_{jk}} \leq 1/\rho_{ij}, \tag{10}$$

ince the correlations with subjective recog- ition (f_i) are less than or equal to 1.0, and Equation 10 is equivalent to the following:

$$f_i f_j \leq f_i/f_j \leq 1/f_i f_j. \tag{11}$$

For example, the single-mediator model would ot be able to account for correlations for $_{LR}$, ρ_{LA}, and ρ_{RA} of .7, .7, and .35, respec- ively, since $\rho_{LA}/\rho_{RA} = 2$, which is outside he limits set by .7 and 1/.7. However, Equa- ion 10 was satisfied for exposure, affect, and ny of the three recognition measures for both xperiments.

These analyses show that the regression nd partial correlation results reported by Moreland and Zajonc (1977) can be explained y the null hypothesis of a single mediator. Good fit of the null hypothesis (Expression 8) hat recognition mediates the exposure effect oes not rule out the possible presence of nconscious affect (as in Expression 9). How- ver, the burden of proof clearly remains on hose who would conclude, with Moreland nd Zajonc (1977, p. 191), that "the relation- hip between stimulus exposure and affect oes not depend on the operation of higher rder cognitive processes."

Parallel With Subception

The present issue has interesting parallels n perception (Garner, Hake, & Eriksen, 1956) nd learning (Dulany, 1968). Eriksen (1956, 960) replicated and reinterpreted an experi- ent of Lazarus and McCleary (1951) that laimed to demonstrate subception. In Erik- en's (1956) replication, subjects were trained to give a verbal response to each of several squares, one of which was paired with shock. In the testing phase, galvanic skin response (GSR) and verbal responses were measured to each stimulus. It was found that the stimulus–GSR relationship was maintained when verbal response was partialed out. Eriksen (1960) noted that the results are consistent with the hypothesis that the stimulus leads to a perception that is imperfectly correlated with the two dependent variables with uncorrelated errors. To find an *absence* of the partial correlation between stimulus and GSR with verbal response partialed out would require that the verbal response be perfectly correlated with perception. In terms of Thurstone's law of categorical judgment, the category boundaries would have to show zero variance. Should the subject shift the limens during the experiment, the partial correlation will be expected to be non-zero.

Causation and Correlation

Brewer, Campbell, and Crano (1970) have cautioned against the use of multiple regression and partial correlation in nonexperimental settings. They reviewed 10 psychological studies in which partial correlations had been used inappropriately to argue for multiple effects without testing the rival, one-factor hypothesis. This paper shows that the criticisms of partial correlation analysis made by Brewer et al. (1970) can apply to certain experimental as well as nonexperimental studies.

Although factor and path analyses may be useful for examining the number and nature of the *effects* in the dependent variables, they do not allow one to draw inferences about causation. Unless the variables are experimentally manipulated, numerous alternative causal models remain consistent with the data. To argue for *multiple causes*, an investigator must demonstrate that *two* or more experimentally *manipulated* variables contribute independently to the measured dependent variables. One should not draw causal inferences from correlations unless the independent variables are truly independent, that is, manipulated experimental variables.

Conclusions

The present article shows that the one-mediator model may be a reasonable null hypothesis for data obtained in experimental studies in which one variable is manipulated and several are measured. Indeed, a positive partial correlation between exposure frequency and liking with rated familiarity partialed out does *not* evaluate the null hypothesis that a single variable mediates the effect of the independent variable on both dependent variables, as shown by Equation 7. Thus, the theory that stimulus recognition mediates the exposure effect on liking is not refuted by the partial correlation and regression analyses of Moreland and Zajonc (1977).

A Psychological Taxonomy of Trait-Descriptive Terms: The Interpersonal Domain

Jerry S. Wiggins
University of British Columbia, Vancouver, Canada

The eventual aim of the research reported is the development of a comprehensive taxonomy of trait-descriptive terms in the English language. Building on earlier work of Allport, Norman, and Goldberg, preliminary a priori distinctions were made among different domains of trait categories. General procedures for developing structured taxonomies within domains were illustrated with reference to the interpersonal domain. Theoretical considerations dictated the definition of the universe of content, the choice of measurement model, and the procedures for classifying terms within the domain. Eight adjectival scales were developed as markers of the principal vectors of the interpersonal domain. The substantive, structural, and psychometric characteristics of these scales were found to be highly satisfactory. Hence, they may prove useful both as assessment devices in their own right and as reference points for the classification of variables in personality and social psychology.

Personality is that branch of psychology which is concerned with providing a systematic account of the ways in which individuals differ from one another (Wiggins, Renner, Clore, & Rose, 1971). Individuals differ from one another in a variety of ways: their anatomical and physiognomic characteristics; their personal appearance, grooming, and manner of dress; their social backgrounds, roles, and other demographic characteristics; their effect on others or social stimulus value; and at any given moment in time, their temporary states, moods, attitudes, and activities. But the principal goal of personality study is to provide a systematic account of individual differences in human *tendencies* (proclivities, propensities, dispositions, inclinations) to act or not to act in certain ways on certain occasions.

Although such tendencies are commonly called "traits," the use of that term in contemporary psychological discourse carries with it implications of a particular theoretical commitment, a preferred method of scientific investigation, and a philosophical preference for certain kinds of explanation in theory construction. Hence, it is necessary to make it clear at the outset that an interest in human tendencies (traits) does not imply a theoretical precommitment to such issues as whether traits are manifestations of generative or causal mechanisms (Allport, 1937); whether trait attributions reflect specific cognitive processes of observers (Heider, 1958); whether traits are best construed idiographically or nomothetically (Allport, 1937; Bem & Allen, 1974; Kelly, 1955); or whether consistencies in human tendencies are largely due to environmental or situational constancies (Mischel, 1968).

In my view, consistent patterns of human conduct constitute the *basic data of personality study,* which require rather than provide explanation (Wiggins, Note 1). In approach-

The early stages of this research were supported by Grant MH 12972 from the National Institute of Mental Health, U.S. Public Health Service (Lewis R. Goldberg, principal investigator). More recent work was supported by Canada Council Research Grant S75-0109. An earlier version of this article was presented at the meeting of the Society of Multivariate Experimental Psychology, Gleneden Beach, Oregon, November 1975.

ing this task of accounting for individual differences in human tendencies, I share with others the conviction that the natural language provides a convenient starting place (Allport, 1937; Cattell, 1957; Goldberg, Note 2; Norman, Note 3). The universe of content of human tendencies is contained within the covers of an unabridged dictionary of the English language. I also share with these writers the conviction that an adequate taxonomy of trait-descriptive terms must precede meaningful empirical studies of human tendencies. There have been a number of systematic efforts to develop a personality taxonomy over the past 40 years, and my own work has attempted to capitalize on these earlier efforts.

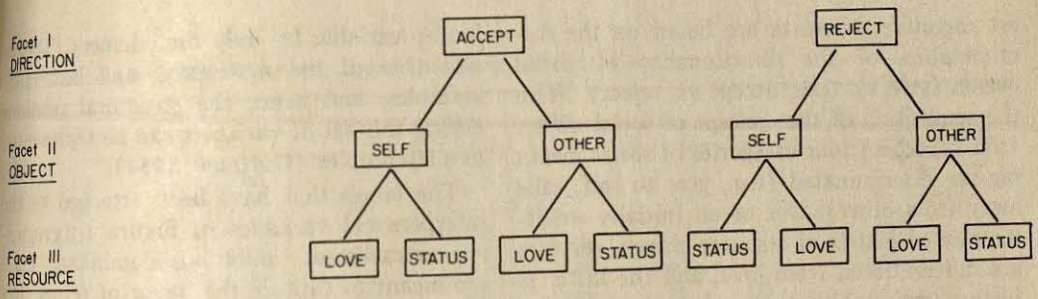
Allport and Odbert (1936) examined the approximately half million separate entries or derivatives included in *Webster's New International Dictionary* (1924) for terms that appeared "to distinguish the behavior of one human being from that of another" (p. 24) and identified a pool of 17,953 terms having this characteristic. Norman (Note 3) scanned the entire contents of *Webster's Third New International Dictionary Unabridged* (1961) for additional terms that had not been included in the Allport–Odbert list. The universe of content thus defined was approximately 27,000 terms. Subsequently, Norman and Goldberg were able to reduce this list by eliminating obscure, inappropriate, and archaic terms. The focus of all of these investigations has been on a subset of approximately 3,600 terms that Allport initially called "stable biophysical traits." Allport considered these to be "real" traits as opposed to temporary states, moods, social roles, physical characteristics, and so forth.

However one conceives of stable biophysical traits, I see them as no more nor less real than any other kinds of human characteristics. I agree with Guilford (1959) that "a trait is any distinguishable, relatively enduring way in which one individual differs from others" (p. 6). But I see the major taxonomic task as that of specifying the different *kinds* of ways in which individuals differ from each other. One *kind* of way in which individuals differ from each other is in terms of what they do to each other. Thus, I think that one of the most important categories of traits is that which may be designated "interpersonal." Within the realm of things that people do to each other, it is desirable to make a further theoretical distinction between interpersonal exchanges based on love and status and interpersonal exchanges based on goods, money, and services (Foa & Foa, 1974). The former are called interpersonal traits and the latter material traits.

Another equally "real" way in which individuals are distinguishable from one another is in terms of their styles of emotional reactivity, which we refer to as "temperament." It is also possible to distinguish individuals on the basis of the particular roles and status they hold within the framework of our social institutions. Additionally, there are "character" terms that represent appraisals of an individual based on a code of proper behavior. And finally, there are many words that refer to individual differences in qualities of mind as manifested in thought, perception, and speech.

Consider the following trait-descriptive adjectives: *aggressive, miserly, lively, ceremonious, dishonest,* and *analytical.* I would classify these terms as representative of the six trait categories just mentioned, namely, interpersonal traits, material traits, temperamental traits, social roles, character, and mental predicates. Here I differ from Allport, Norman, and Goldberg, who view all of these terms as "stable biophysical traits," without attempting to differentiate the different kinds of descriptive jobs such terms perform for us. To these earlier authors' important distinction between stable traits and temporary states, moods, social evaluations, and so forth, I would add finer distinctions *within* the category of stable traits.

The present article describes our first efforts to develop a taxonomy of personality trait-descriptive terms in the English language. The universe of content is taken to be Norman's (Note 3) total lexicon of 18,125 terms. Within this broader framework, I intend to focus on the "prime" categories of Norman, which involve 4,063 relatively familiar and nonobscure terms. Even restricting our attention to prime terms, we are still



INTERPERSONAL VARIABLES								
NO (Gregarious - Extraverted)	+	+	+	+				−
PA (Ambitious - Dominant)	+	+	+				−	−
BC (Arrogant - Calculating)	+	+				−	−	−
DE (Cold - Quarrelsome)		+			−	−	−	−
FG (Aloof - Introverted)				+	−	−	−	
HI (Lazy - Submissive)			+	+	−	−		
JK (Unassuming - Ingenuous)			+	+	−			
LM (Warm - Agreeable)	+		+					

Figure 1. Facet composition of interpersonal variables (after Foa & Foa, 1974). (+ = acceptance; − = rejection.)

confronted with a list of staggering size. Our enterprise required a clear-cut game plan or research strategy to guide us through this sea of words.

We began by defining a limited taxonomy on an a priori basis. We attempted to specify different *domains* of human characteristics based on the different descriptive jobs performed by the words within the domains. Next, we attempted preliminary a priori classifications within domains, mainly as a means of keeping track of terms and lightening our clerical burdens. The overall strategy for developing a taxonomy within a single domain may be honorifically described as "iterative," although "trial and error" may be a more apt descriptor. Our main concern was the avoidance of premature "fixing" of a taxonomy. Hence, all preliminary classifications were tentative in nature and subject to continual revision in the light of other developing categories. This rather complex interactive strategy will be illustrated with reference to the development of a taxonomy within the domain of interpersonal traits.

The Domain of Interpersonal Traits

The line of reasoning to be presented originated in the interpersonal theory of Sullivan (1953) and was later operationalized in a set of personality measurement procedures by Leary (1957) and his colleagues. Foa (1961, 1965) integrated this theory with Guttman's (1954) order analysis, and the general orientation was extended to domains other than the interpersonal by Rinn (1965). Notable interpersonal systems based on a circumplex model have also been described by Becker and Krug (1964), Benjamin (1974), Lorr and McNair (1963), Schaefer (1959), and Stern (1970). This general framework was integrated with interpersonal exchange theory (Homans, 1961) by Carson (1969) and by Foa and Foa (1974).

In their most recent theoretical statement, Foa and Foa (1974) describe the development of cognitive categories of social perception as a progressive differentiation of structure involving facets of *directionality*, *object*, and *resource*. A somewhat simplified version of Foa and Foa's representation of this structure is illustrated at the top of Figure 1. The earli-

est cognitive schemata are based on the discrimination of the directionality of social events (give vs. take, accept vs. reject). With the acquisition of the concept of social object (self vs. other) four categories of social meaning are discriminated (e.g., give to self, take away from other). Out of an initially undifferentiated matrix of resource classes, services are differentiated from love, and the latter is further differentiated into love and status. With the distinction between love and status, earlier facets become reorganized, and it is possible to distinguish eight features of social meaning (e.g., granting status to oneself, denying love to another). These eight features may be thought of as part of a semantic code strip that provides the basic discriminations for encoding and decoding interpersonal events (Osgood, 1970).

Within the above context, interpersonal events may be defined as *dyadic interactions that have relatively clear-cut social (status) and emotional (love) consequences for both participants (self and other)*. This definition provides a theoretical basis for distinguishing interpersonal traits from other categories of trait descriptors, such as temperament, moods, cognitive traits, and physical characteristics.

Under the semantic features in Figure 1 are listed eight theoretical interpersonal *variables*. The organization of these variables is thought to be determined by an interrelated set of societal rules that impart meaning to social events (Wiggins, Note 1). Thus, actions that have the same profile of semantic features are categorized as belonging to the same response class. The semantic features of each of the eight variables appear as rows in Figure 1. Note that the first variable (NO) is coded on all the positive (accept) categories for self and other with respect to both love and status. The first variable is in marked contrast to FG for which all values are negative (reject). Variables NO and FG have no features in common, but since acceptance and rejection are logically opposed concepts, it would be expected that the two variables would be strongly negatively correlated. Similar relationships can be seen to exist between PA and HI, BC and JK, and DE and LM. Note also that each variable differs from its adjacent variable by only one element. This is also true of the first (NO) and last (LM) variables, and hence the structural relations among this set of variables can be represented as a circumplex (Guttman, 1954).

The labels that have been attached to the interpersonal variables in Figure 1 (gregarious–extraverted, ambitious–dominant, etc.) are meant to capture the flavor of terms that share the same profile of semantic features and may serve more as tags than as definitions. Thus, for example, the rather inelegant label of "lazy–submissive" is attached to interpersonal transactions involving incompetence, passive resistance, submission, or obedience. These otherwise diverse attributes share in common the semantic features of denying status to self, denying love to both self and other, and granting status to other. A fuller listing of representative terms in each category may be found in Table 2, later in this article.

Were we to collect personality measurements on the eight variables listed in Figure 1, their intercorrelations would, in theory, show the pattern illustrated in Table 1. The correlation of a variable with itself is assumed to be unity, so that the principal diagonal of this matrix contains ones. The correlations along this main diagonal are large and positive, and they decrease across successive minor diagonals to the $n/2$nd variable, where they are a minimum. The correlations then increase up to a large positive value in the off-diagonal matrix. The circumplexity of this or any other set of variables can be evaluated directly from the intercorrelation matrix. A rigorous procedure for assessing the circumplexity of a set of variables involves plotting the correlations of each variable (ordinate) with the other variables in sequence (abscissa). This procedure should generate a series of overlapping sine curves that can be evaluated for goodness of fit (Stern, 1970).

An alternative procedure for evaluating circumplexity is to extract the first two principal components from the matrix of intercorrelations and to examine the plot of the variables on the two components. Figure 2 presents the plot of the eight variables on two principal

Table 1
Hypothetical Correlations Among Eight Interpersonal Variables

Variable	PA	BC	DE	FG	HI	JK	LM	NO
PA	1.00							
BC	.50	1.00						
DE	.00	.50	1.00					
FG	−.50	.00	.50	1.00				
HI	−1.00	−.50	.00	.50	1.00			
JK	−.50	−1.00	−.50	.00	.50	1.00		
LM	.00	−.50	−1.00	−.50	.00	.50	1.00	
NO	.50	.00	−.50	−1.00	−.50	.00	.50	1.00

components extracted from the intercorrelations in Table 1. As can be seen from this figure, the intercorrelations among variables in Table 1 form a perfect, equally spaced circumplex. This pattern follows, both theoretically and empirically, from the pattern of shared semantic features among the variables illustrated at the bottom of Figure 1. Variables that share three features in common are adjacent to each other on the circle; variables that have no features in common are opposite each other.

There are two distinct advantages to the representation of interpersonal variables by a two-dimensional circumplex. The first is that it provides an explicit conceptual definition of the universe of content of interpersonal behavior. Any behavior that meets the definition of a meaningful interpersonal event given above must be capable of being represented as a vector originating from the center of the circle. Thus, the specific system proposed here is potentially falsifiable. The second advantage of the circumplex model is that it

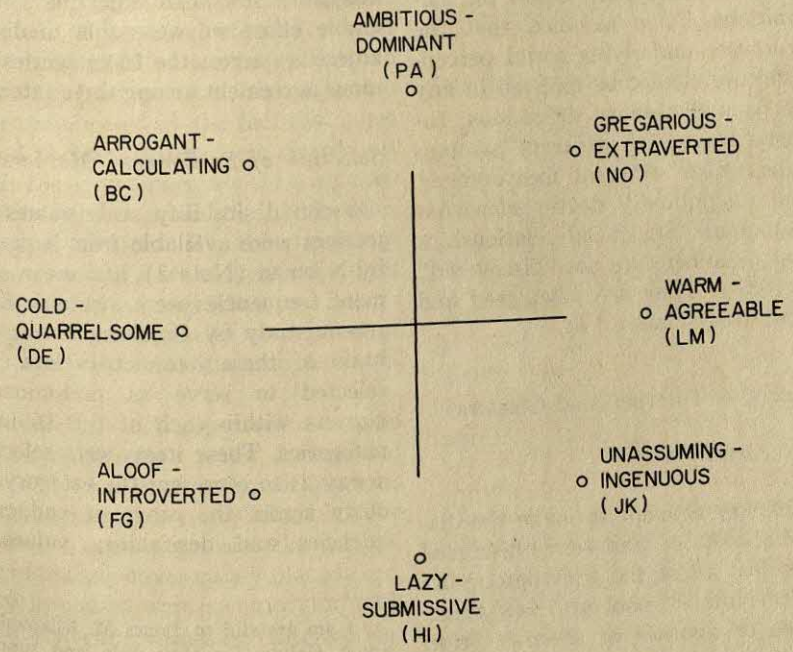

Figure 2. Perfect circumplex of interpersonal variables.

alerts the investigator to noticeable "gaps" in the interpersonal space of a given set of variables. Strictly empirical procedures of variable selection are likely to deemphasize the importance of certain variables that are implied by the logic of the circumplex system but that are underrepresented in the English language. Although the system of interpersonal variables under discussion is limited to eight variables, it could in principle be equally well represented by 16, 32, or 64 variables. The thinness with which we slice the circumplex pie is limited by the reliability with which respondents can distinguish between closely synonymous words or phrases.

It should be evident that the preceding theoretical considerations substantially constrain the final form that a taxonomy of interpersonal traits may assume. The definition of interpersonal events, the specification of their underlying facet structure, and the selection of a measurement model to represent relationships among variables all express a commitment to a particular, albeit widely shared, conceptualization of the domain under investigation. In this sense, the eventual taxonomy of trait-descriptive terms will be a "psychological" taxonomy rather than a strictly "semantic" taxonomy based on dictionary definitions. It is assumed that the semantic structures underlying social perception in this culture cannot be inferred in any obvious way from dictionary definitions. Investigators who start with different assumptions and who utilize different measurement models would undoubtedly devise somewhat different taxonomies. Structural relationships of the kind at issue here are not "discovered" (Loevinger, 1957). They are postulated and then evaluated for goodness of fit.

Development of Interpersonal Clusters

Rational Categorization

In a preliminary attempt to make the distinction among *kinds* of trait terms discussed above, I classified all of the trait descriptors in Goldberg's (Note 2) pool of 1,710 adjectives into one or another of seven a priori categories. At that stage in the development of the taxonomy, the principal distinctions were between interpersonal trait terms, temperamental trait terms, and mental predicate terms. Tentative categories of "attitudinal terms" and "constancy" were employed at this point, as well as a "miscellaneous" category that involved various dimensions that could not be clearly classified into other categories. In the initial sorting of the 1,710 adjectives, approximately 800 terms were identified as "interpersonal" under our working definition of interpersonal traits.

For purposes of preliminary categorization, we selected Leary's (1957) system of interpersonal traits, because it appeared to be the most explicit system described in the literature, an entire book being devoted to the topic. Two colleagues [1] and I thoroughly familiarized ourselves with the system and its theoretical framework. Working as a team, we considered each of the approximately 800 terms previously classified as interpersonal and attempted to classify each within one of the 16 interpersonal vectors. Adjectives that could not be classified within the 16 dimensions and that did not appear to belong in one of the other five a priori categories were temporarily set aside for further analysis. There were remarkably few such adjectives. With considerable effort we were able to distribute 567 adjectives across the 16 categories with unanimous agreement among three raters.

Selection of Preliminary Markers

Social desirability scale values for all adjectives were available from a previous study by Norman (Note 2), and mean self-endorsement frequencies were available from a more recent study by Goldberg (Note 2). On the basis of these itemmetric data, items were selected to serve as preliminary nuclear clusters within each of the 16 interpersonal categories. These items were selected in such a way as to represent the category unambiguously across the range of endorsement frequencies and desirability values. Approxi-

[1] I am grateful to James M. Kilkowski and Alexander Galvin for their help and support in this enterprise.

mately 12 items were selected for each category.

In Goldberg's sample of 70 male and 117 female University of Oregon undergraduates, self-ratings were obtained on a 9-place scale for each of the 1,710 trait descriptors. Using Goldberg's data, our next step was to obtain the intercorrelations among terms selected to be preliminary markers of each of the categories of interpersonal behavior. By a clustering procedure, a smaller and more homogeneous subset of items was selected within each category, with approximately six items per cluster.

The next step was to consider all items that had been rationally classified as falling within the 16 categories as potential candidates for addition to or deletion from each nuclear interpersonal cluster. For this purpose, we scored the preliminary clusters as 16 scales and examined the correlations of individual items with these scales with an eye toward their circumplex patterning. Thus, we examined the correlation of each of the 567 items with the 16 preliminary clusters ordered by their hypothetical position in the circumplex. Items were sought that had positive correlations with adjacent clusters, zero correlations with orthogonal clusters, and negative correlations with opposite clusters. For most items, this circumplex patterning across 16 clusters was far from perfect. Item selection was further complicated by the fact that some of the initial nuclear clusters were clearly out of place on the circumplex, so that we constantly had to keep in mind the inadequacies of our original clusters. By this bootstrap procedure, we selected a set of eight adjectives for each of the 16 vectors that, we hoped, would increase the homogeneity of their vector and correct the previous shortcomings of that vector.

We assembled the 128 adjectives chosen to mark the 16 vectors into a test format and administered it to a small group of students from the University of British Columbia. The students were requested to rate the self-applicability of the adjectives on a 9-place Likert scale. Item responses were summed for both octant and sixteenth variables. Intercorrelations among the variables were factored by the method of principal components. Figure 3 displays the pattern of octant variables loading on the first two factors in the University of British Columbia sample. The pattern of loadings for 16 interpersonal variables is considerably less orderly than this, due no doubt to the fact that the vector scores are based on fewer items in a relatively small sample of subjects. But the pattern of octant scores clearly displays some of the difficulties we encountered in our attempt to map out Leary's (1957) system.

The most striking feature of Figure 3 is the lack of variables in the upper right-hand quadrant. This gap in the Leary (1957) circumplex has been previously noted by several authors including Stern (1970), who felt that the failure of Octants PA and NO to "close" raises the question of whether the Leary system is a circumplex. Lorr and McNair (1965) noted this gap also and attempted to close it with additional substantive variables. Another notable departure from expectations is the location of Octant NO, which not only fails to appear in the upper quadrant but appears *below* Octant LM. In a sense, then, we partially succeeded in replicating the Leary system with trait-descriptive adjectives, but in so doing we carried over the faults of the system as well.[2]

Development of Bipolar Clusters

At this point it occurred to us that a 16-variable circumplex can be rather easily constructed from eight genuine *bipolar* dimensions. One of the conceptual difficulties we experienced in working with the Leary system was a decided lack of bipolarity between vectors that appeared opposite each other on the circle. In particular, the following implicitly bipolar contrasts did not make a great deal of sense: success versus masochism, narcissism versus conformity, rebellion versus

---

[2] Juris I. Berzins (personal communication, March 8, 1977) plotted the loadings of the original Leary (1957) Interpersonal Checklist (ICL) octants on the first two principal components in samples of 685 high school students and 1,109 college students. The plots for both samples are indistinguishable from Figure 3. (See also Rinn, 1965, p. 458, Figure 6.)

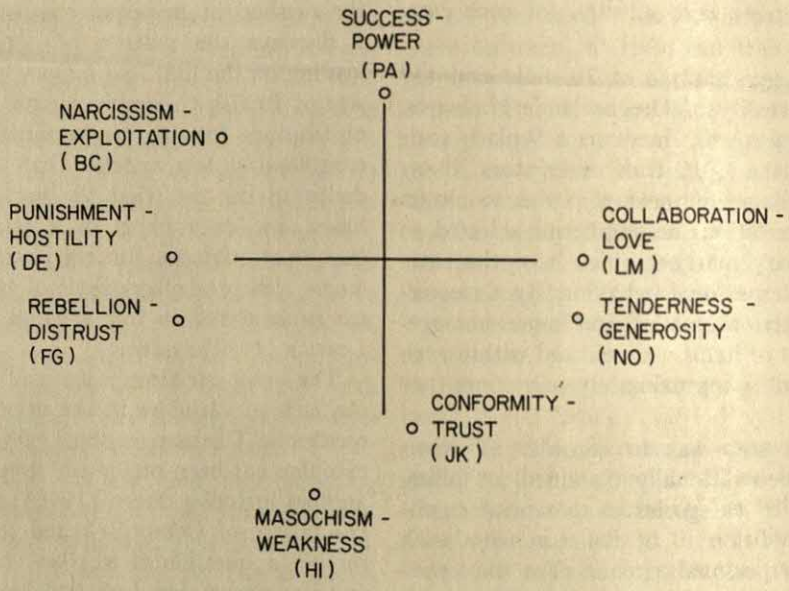

Figure 3. Rotated components of Leary (1957) interpersonal variables.

tenderness, distrust versus generosity, and punishment versus collaboration.

In Leary's (1957) original system the tenderness–generosity octant (NO) was conceptualized as the bipolar contrast to the rebellious–distrustful octant (FG). This likely accounts for the noticeable gap in the upper right quadrant of the system (Figure 3). Tenderness and generosity are not bipolar contrasts to rebellious and distrustful behavior. Tenderness and generosity are too weak and loving to be placed this high on the circle. As Lorr and McNair (1965) noted earlier, the NO octant, which falls between dominance and love, reflects a socially exhibitionistic style of behaving (gregarious–extraverted).

With a little effort, our revised representation of the 16 interpersonal variables can be read from Figure 2. Each variable represents a bipolar contrast to the variable appearing opposite it on the circle. The contrasts are dominant–submissive, arrogant–unassuming, calculating–ingenuous, cold–warm, quarrelsome–agreeable, aloof–gregarious, introverted–extraverted, and ambitious–lazy.

In developing our bipolar clusters, we attempted to select items that were highly negatively correlated with their opposite cluster and that had zero correlations with their theoretically orthogonal clusters. Thus, a good dominant item should have a high positive correlation with a dominant cluster, a high negative correlation with a submissive cluster, and essentially zero correlations with quarrelsome and agreeable clusters. We used a tentative set of 16 four-item bipolar clusters as markers to select items having the properties just described. This enabled us to revise and expand our tentative clusters into eight-item variables. Factor analysis of these eight-item variables in Goldberg's (Note 2) sample of 187 subjects revealed the clearest circumplex structure we had yet encountered in our own work or in the literature. This result was replicated in an additional sample of 119 subjects from the University of British Columbia.

Development of Final Scales

The items in our eight-item bipolar interpersonal clusters were developed from the pool of 567 adjectives classified as interpersonal in our initial rational sorting of the total list of 1,710 adjectives. The possibility clearly existed that some adjectives from among the 1,143 not considered would be appropriately placed within the 16 interper-

sonal categories. Consequently, a program was written to examine the relationships between all 1,710 adjectives and the 16 bipolar interpersonal clusters. The program correlates each adjective with the 16 bipolar clusters, selects the cluster with which the adjective is most highly correlated, and then prints out an ordered list of variables within each of the 16 categories. This listing provided the correlation of each item with the cluster with which it was most highly correlated. It also provided the correlation with the bipolar opposite cluster and with the two orthogonal clusters. This procedure produced 16 lists that located all 1,710 adjectives with respect to the interpersonal cluster with which they were most highly correlated.

Two of us then went through these lists and examined the correlation of each item with the cluster from the category to which it had been assigned, as well as the correlation of the item with its opposite and orthogonal clusters.[3] Items that clearly belonged in the interpersonal category to which they had been assigned were retained. Items that did not appear to belong in the interpersonal category to which they were assigned were placed in one of eight other taxonomic categories that then existed (e.g., temperament, character, material traits, etc.).

At this point, an attempt was made to develop more refined subcategories within the broader taxa. Preliminary groupings of clusters were formed within the domains of temperament, character, attitudes, mental predicates, and social roles. This classification added 38 new clusters to the 16 interpersonal clusters, making a total of 54 categories within the preliminary taxonomy. These 54 categories were scored as scales by computing, for each subject, the sum of his or her ratings to the items in that category. In the case of the 16 interpersonal categories, the 25 best items, as determined from item–cluster correlations, form the reference scale for each category.

The next stage of analysis was designed to determine more exactly the classification of doubtful adjectives in the preceding taxonomic sort. This included adjectives that were interpersonal but that seemed to be in the wrong interpersonal category, adjectives that were unclassifiable in any category, and adjectives that were candidates for deletion on the grounds of ambiguity, obscurity, or lack of personological relevance. In addition, all adjectives in the interpersonal category other than the 400 (16×25) marker adjectives were classified as doubtful for the purpose of this analysis. There were 768 such adjectives designated as questionable by this criterion. Each of the 768 adjectives was correlated with all of the 54 taxonomic category scales. Two of us then examined this pattern of correlations for all 768 words and assigned them to one of the 54 categories on the basis of both conceptual and empirical (correlational) considerations. Some items were retained in their original interpersonal category, others moved to other categories, and some deleted from further consideration. By these procedures, a revised 54-category taxonomy was developed. Within this revised taxonomy, 864 adjectives were classified as interpersonal.

The selection of items for inclusion in the final interpersonal trait scales involved one more cycle in our iterative procedures The 25 "best" items previously identified in each of the 16 interpersonal categories were scored as reference clusters. These reference clusters provided a broader representation of the content of the final interpersonal variables than did our earlier clusters. Within each category, each item was correlated with its own 25-item cluster and with its 25-item opposite and orthogonal clusters. The items were then ordered within each category by their correlations with their own clusters.

Working independently, three of us selected the "best" eight items in each of the 16 interpersonal categories. One rater made selections strictly on the basis of a summary numerical index based on item correlations with same, opposite, and orthogonal clusters, a procedure referred to as *empirical*. Another rater attended to the same item correlations, but attempted to choose the more "meaningful" adjectives from pairs that had roughly similar empirical characteristics, a procedure

---

[3] I would like to acknowledge the substantial help of Ana Holzmuller in this and many other phases of the project.

designated *quasi-empirical*. The third rater selected sets of eight adjectives that were "psychologically cohesive" in terms of his conception of the constructs under investigation, the *rational* procedure.

The empirical and quasi-empirical item-selection procedures yielded sets of 16 scales with highly similar psychometric properties. For a specific sixteenth, it was possible to identify one or the other of the two scales as being preferable, either on grounds of a higher alpha coefficient or on the grounds of a better position in the 16-variable circumplex plot. Consequently, a *combination* set of 8 variables was formed from the best of the empirical and quasiempirical sixteenths.

An additional procedure for item selection was based on a more fine-grained analysis of the circumplex properties of individual *items*. Each item was correlated with the 16 25-item clusters that served as markers of the interpersonal variables. This *pattern* of correlations was then inspected for the number of departures from perfect circumplex ordering that occurred. Items with the smallest number of departures from this pattern were retained in a set of scales labeled "item ordering."

The final selection of a 128-item set of interpersonal variables was based on an index of circumplexity that permits comparison among competing scale sets (Wiggins & Marston, Note 4). Very briefly, two factors were extracted from the intercorrelations among interpersonal variables in a given scale set. A hypothetical factor matrix was constructed to represent a perfect circumplex solution for variables of this level of reliability (as estimated from communalities). The sum of the absolute differences between elements in the hypothetical factor matrix and elements in the obtained factor matrix was taken as an index of circumplexity. Each of the five sets of interpersonal scales was then compared on this index. Both octants and sixteenths were evaluated in Goldberg's (Note 2) sample of 187 University of Oregon undergraduates and in Norman's sample of 123 University of Western Australia undergraduates. An overall index of circumplexity, based on both 8- and 16-variable solutions in American and Australian samples, suggested that the *combination* set of 128 adjectives had a slight edge over the item-ordering, empirical, and quasi-empirical procedures and a substantial advantage over the rational procedure, which fared rather badly. This combination set of adjectives, which has been employed in all subsequent investigations, is listed in Table 2.

Generalizability of Circumplex Structure

The present taxonomy of the interpersonal domain is based on an explicit structural model (Guttman, 1954) that follows from a facet analysis of cognitive categories of social perception (Foa & Foa, 1974). On the basis of both theoretical and psychometric considerations, a set of eight 16-item scales were developed as marker variables of the principal vectors of this system. In addition to being potentially useful personality assessment measures in their own right, these scales enable one to classify any interpersonal trait descriptor by establishing its location within the circumplex space. However, the meaningfulness of such classification depends heavily on the generalizability of the present circumplex structure to samples other than those involved in the derivation of the eight interpersonal scales. The scales were derived primarily from Goldberg's (Note 2) sample of American students and cross-validated at various stages in samples of Canadian students and in Norman's sample of Australian students. Although relatively diverse samples of students were employed in scale derivation, evidence for the generalizability of the circumplex structure must come from other sources. Four samples of subjects were tested for this purpose.

Cross-Validation Samples

Sample A. Subjects were recruited by advertisements to participate in a "personality study" that involved two separate testing sessions of approximately 2 hours each (Marston, Note 5). Subjects were paid $10 each for their participation and were provided individual feedback if requested. The 128 interpersonal adjectives were embedded in a

Table 2
Final Set of Interpersonal Adjective Scales

P. **Ambitious** (Success)	A. **Dominant** (Power)	B. **Arrogant** (Narcissism)	C. **Calculating** (Exploitation)
Persevering	Dominant	Bigheaded	Sly
Persistent	Assertive	Boisterous	Tricky
Industrious	Forceful	Conceited	Wily
Self-disciplined	Domineering	Boastful	Cunning
Organized	Firm	Overforward	Overcunning
Deliberative	Self-confident	Swellheaded	Crafty
Stable	Self-assured	Cocky	Calculating
Steady	Un-self-conscious	Flaunty	Exploitative
D. **Cold** (Hate)	E. **Quarrelsome** (Hostility)	F. **Aloof** (Disaffiliation)	G. **Introverted** (Withdrawal)
Warmthless	Impolite	Antisocial	Silent
Unsympathetic	Uncordial	Unneighborly	Shy
Ironhearted	Discourteous	Impersonal	Introverted
Uncharitable	Ungracious	Unsociable	Bashful
Coldhearted	Disrespectful	Distant	Inward
Hardhearted	Uncooperative	Dissocial	Unrevealing
Cruel	Ill-mannered	Unsmiling	Unsparkling
Ruthless	Uncivil	Uncheery	Undemonstrative
H. **Lazy** (Failure)	I. **Submissive** (Weakness)	J. **Unassuming** (Modesty)	K. **Ingenuous** (Trust)
Unproductive	Self-doubting	Nonegotistical	Uncunning
Lazy	Self-effacing	Undemanding	Uncalculating
Unthorough	Timid	Unvain	Uncrafty

L. **Warm** (Love)	M. **Agreeable** (Collaboration)	N. **Gregarious** (Affiliation)	O. **Extraverted** (Outgoingness)
Tenderhearted	Courteous	Friendly	Outgoing
Gentlehearted	Charitable	Genial	Extraverted
Tender	Well-mannered	Neighborly	Vivacious
Kind	Respectful	Companionable	Jovial
Emotional	Cordial	Approachable	Enthusiastic
Sympathetic	Cooperative	Congenial	Cheerful
Softhearted	Accommodating	Good-natured	Perky
Appreciative	Forgiving	Pleasant	Unshy

list of 605 adjectives whose order was randomized separately for each subject. Four personality inventories were administered in varying orders along with the total list of adjectives. The 152 subjects (51 men and 101 women) included both undergraduate and graduate students from a variety of academic majors at the University of British Columbia.

Sample B. Representative samples of volunteer and professional workers were recruited from three different social service agencies in the Greater Vancouver area (Merritt, Note 6). The 128 interpersonal adjectives were administered in a single booklet along with a value survey and a standardized personality inventory. Testing was accomplished individually, in small groups, or on a take-home basis. One hundred subjects (29 men and 71 women) completed the interpersonal adjective form.

Sample C. Students in the second term of an introductory psychology class at the Uni-

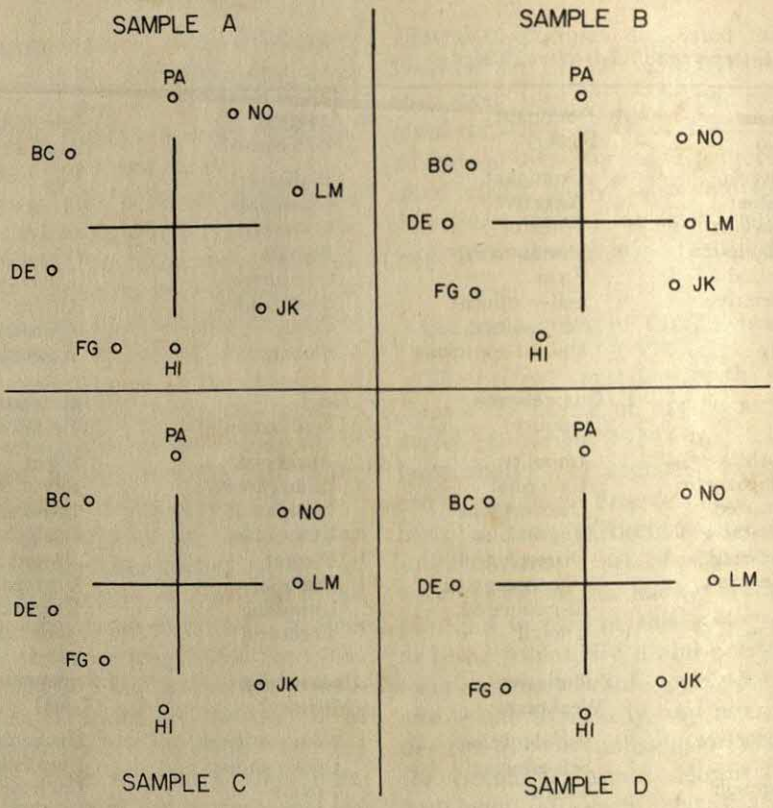

Figure 4. Structure of final interpersonal variables in four samples. (PA = ambitious-dominant; BC = arrogant-calculating; DE = cold-quarrelsome; FG = aloof-introverted; HI = lazy-submissive; JK = unassuming-ingenuous; LM = warm-agreeable.)

versity of British Columbia were administered the 128 adjectives, embedded in a larger list of adjectives, during a regular class period. The students were given a guest lecture on personality testing in exchange for their participation. Data were collected for 132 subjects (57 men and 75 women).

Sample D. Summer students enrolled in an introductory psychology class at the University of British Columbia were administered the 128 adjectives, embedded in a larger list, during a regular class period. The students later received their own standardized scores on the interpersonal variables and a lecture on interpersonal behavior. Data were collected for 139 subjects (58 men and 81 women).

Circumplex Analyses

Intercorrelations were obtained among the eight interpersonal adjective scales in each of the four samples just described. Two principal components were then extracted from each of the intercorrelation matrices. In the respective analyses, these two components accounted for 76.1% (Sample A), 67.9% (Sample B, 72.0% (Sample C), and 74.8% (Sample D) of the total variance. For comparability of inspection, the second component of each solution was hand rotated to pass through the ambitious–dominant vector (PA). Figure 4 depicts the loadings of the eight interpersonal scales on two hand-rotated principal components in each of four samples.

Perfect, evenly spaced circumplexes (Figure 2) are not expected in real data, because of measurement error, and hence the structures in Figure 4 are more properly described as quasi-circumplexes (Guttman, 1954). Although the amount of "quasiness" one is prepared to tolerate in empirical data is to some extent a matter of taste, it seems fair to say that the quasi-circumplex structures in

Table 3
Psychometric Characteristics of Interpersonal Adjective Scales

Scale label	Scale M and SD[a]						Social desirability rating (N = 100)		Internal consistency (coefficient alpha)	
	Men (n = 236)		Women (n = 374)		Total (N = 610)				Total sample (N = 610)	Range of values from the 4 subsamples
	M	SD	M	SD	M	SD	M	SD		
PA	5.87	.95	5.72	1.01	5.79	.99	6.77	1.10	.855	.831–.880
BC	4.30	1.02	3.60	1.07	3.87	1.05	3.66	.98	.870	.845–.885
DE	2.95	.89	2.48	.80	2.66	.84	2.31	.81	.877	.862–.889
FG	4.28	1.19	3.87	1.17	4.03	1.17	3.54	.71	.891	.887–.894
HI	3.95	.94	4.13	1.01	4.06	.99	3.37	.61	.809	.769–.838
JK	4.64	.93	5.14	1.00	4.95	.97	5.73	.95	.801	.743–.840
LM	6.64	.80	7.08	.76	6.91	.77	7.53	.73	.865	.841–.879
NO	6.17	.96	6.54	.96	6.40	.96	7.52	.66	.897	.887–.917

Note. Scale labels stand for ambitious-dominant (PA); arrogant-calculating (BC); cold-quarrelsome (DE); aloof-introverted (FG); lazy-submissive (HI); unassuming-ingenuous (JK); warm-agreeable (LM); and gregarious-extraverted (NO).
[a] Scale values range from 1 (extremely inaccurate description) to 9 (extremely accurate description).

Figure 4 are among the clearest reported in the personality literature to date. The circumplex ordering obtained in scale derivation samples is generalizable across relatively diverse samples of subjects tested in differing contexts. Hence, the eight scales may prove useful both as measuring instruments and as reference points for the classification of items and scales in the interpersonal domain.

Psychometric Characteristics

Sex Differences

Table 3 presents normative and psychometric data for each of the eight interpersonal adjective scales. The first six columns contain means and standard deviations in a combined sample of 610 North American university students. Inspection of the separate means for men and women reveals clear-cut, and to some extent predictable, sex differences in self-report. In comparison with women, men present themselves as more ambitious–dominant, arrogant–calculating, cold–quarrelsome, and aloof–introverted. Women present themselves as more lazy–submissive, unassuming–ingenuous, warm–agreeable, and gregarious–extraverted. All of these mean differences are statistically reliable. Surprisingly, the smallest differences occur on ambitious–dominant ($p < .03$) and lazy–submissive ($p < .01$); all other differences are highly reliable ($p < .0001$).

Sex differences in self-report on the interpersonal circumplex provide a graphic representation of sex role stereotypes in North American society (Wiggins & Holzmuller, 1978). These differences are sample dependent and may possibly decrease in future years. Samples of university students are not uniformly "stereotyped." They contain differing proportions of complexly "sex-reversed" subjects, such as men who score high on lazy–submissive and on aloof–introverted and women who score high on ambitious–dominant and on gregarious–extraverted (Wiggins & Holzmuller, Note 7).

Social Desirability

Social desirability ratings of the individual adjectives were obtained from Norman's monograph (Note 3). One hundred University of Michigan undergraduates (50 men and 50 women) rated the adjectives on a 9-place social desirability rating scale. The means and standard deviations for the 16 adjectives in each scale appear in columns 7 and 8 of Table 3. Comparing the total-sample mean self-report scale scores with corresponding mean social desirability ratings, it is clear that the well-known relationship between endorsement and desirability is found within the interpersonal domain (Edwards, 1957a). Moreover, the similarity between mean endorsement and mean desirability with respect to the *patterning* or ordering of interpersonal

variables is open to alternative interpretations of the circumplex structure in terms of stylistic response variables.[4]

A variety of procedures have been suggested for coping with the endorsement–desirability confound in self-report personality data. On the assumption that in principle, responses within all interpersonal vectors should be equiprobable, LaForge and Suczek (1955) tried to write desirable phrases for undesirable dimensions ("Can be strict if necessary") and undesirable phrases for desirable dimensions ("Spoils people with kindness"). Jackson's (1970) differential reliability index removes desirability variance and enhances content saturation at the stage of item selection. Norman (Note 9) has described analysis of variance procedures for removing desirability variance from the Subject × Item response matrix. Finally, several individual difference measures of social desirability response style have been constructed to permit the assessment of desirability responding for each subject (e.g., Crowne & Marlowe, 1960; Edwards, 1957b; Wiggins, 1959).

The extent to which an investigator may feel the need to "correct for" the ubiquitous endorsement–desirability confound will vary with the purpose of the investigation and with the investigator's theoretical stance on the meaning of the evaluative dimension of affective meaning. A set of interpersonal variables that did not differ in desirability (or did not reveal sex differences) would be a feeble representation of real-life categories of social perception. On the other hand, basic investigations of the process of responding to personality inventory items may require variance decomposition procedures such as those of Norman (Note 9). In any event, interpretations of individual or group scores on the interpersonal scales should be made with reference to *normative data* of the kind provided in Table 3. Whether a person or a group scores high on warm–agreeable or low on cold–quarrelsome can be judged only with reference to the scores of others.

Internal Consistency

In the selection of item sets to mark the vectors of the interpersonal domain, the principal itemmetric criterion was that of structural fidelity (Loevinger, 1957). By a variety of procedures, we attempted to ensure that each item selected was properly located with reference to a circumplex that we had adopted as the most appropriate measurement model for representing the relationships among categories of interpersonal perception. Items were also selected that had relatively high correlations with appropriate preliminary scales. Final scales thus constructed are likely to be internally consistent, although this must be demonstrated rather than assumed.

The next-to-last column of Table 3 presents coefficient alpha (Cronbach, 1951) estimates of internal consistency for each of the interpersonal scales in a combined sample of university students. The final column of the table indicates the range of alpha coefficients obtained in the four samples that constituted the combined student group. Although some of the interpersonal scales are more reliable than others, all of them meet a reasonably stringent requirement of acceptable internal consistency ($\alpha > .80$). The range of alpha coefficients in the different samples tends to be small, and this, together with the representativeness with which the universe of content was sampled, makes it reasonable to assume that the mean alpha values reported are good estimates of the characteristic degree of interitem structure for the different interpersonal variables (Loevinger, 1957). In this respect, the extraversion–introversion dimension (NO–FG) is the most internally cohesive, and the variables of unassuming–ingenuous (JK) and lazy–submissive (HI) are the least.

Discussion

The long-range goal of the research reported in this article was the development of a psychological taxonomy that would encompass the approximately 4,000 relatively familiar trait-descriptive terms identified by

[4] For example, Douglas N. Jackson (personal communication, November 27, 1975) is convinced that the present interpersonal circumplex structure, as well as others reported in the literature, can be accounted for in terms of his threshold theory of desirability responding (Rogers, 1971; Jackson, Note 8).

Norman (Note 3). The research strategy adopted for this task relied heavily on certain a priori distinctions between different domains of human characteristics. In the present work, the domain of interpersonal traits was defined in such a way as to distinguish it from other domains such as temperament, character, moods, and cognitive traits. These, or similar, distinctions have been made by most personality theorists concerned with taxonomic issues (e.g., Allport, 1937; Cattell, 1950; Murray, 1938). However *within* the interpersonal domain, the adoption of a two-dimensional real-space circumplex model (Benjamin, 1974) to capture the interrelationships among trait terms represents a personal methodological preference that is perhaps not as widely shared. On the basis of the work reported in this article, it seems fair to conclude that the domain of interpersonal trait descriptors *can* be classified, quite precisely, with reference to a circumplex model (a conclusion that was not obvious when we began. Since there are, no doubt, many other ways in which the interpersonal domain could be classified, under different definitions and different models, the specific advantages of the present framework must be discussed in more detail.

Two-dimensional circular orderings of interpersonal variables have been reported in the literature for more than 40 years (Schaefer, 1961), and the general conceptual model underlying this structure can be traced as far back as Galen (Roback, 1928). Remarkable "convergences" in conception and structure have been noted for studies varying widely in variables, populations, and measurement procedures (Foa, 1961; Schaefer, 1961; Wiggins, 1968). These convergences do not stem from the similarity of generative mechanisms postulated by different theorists (needs, interests, dynamisms, etc.) to account for surface patterns. Instead, the convergences reflect a set of semantic categories that impart a common meaning to social events observed by a variety of procedures. The categories distinguished by the ordinary language of personality are not sharply demarcated, and they are perhaps best thought of as "fuzzy sets" (Zadeh, Fu, Tanaka, & Shimura, 1975) rather than as precise logical distinctions. The circumplex model appears to be particularly well suited for representing elements (in the present case, adjectives) whose class membership is continuous rather than discrete.

Although often working in apparent isolation from one another, numerous investigators have proposed highly similar models of interpersonal behavior for the study of parents (Chance, 1959; Roe & Siegelman, 1963; Schaefer, 1959), children (Baumrind & Black, 1967; Becker & Krug, 1964; Schaefer & Bayley, 1963), parents and children (Benjamin, 1974; Foa, Triandis, & Katz, 1966), normal and abnormal adults (Leary, 1957; Lorr & McNair, 1963), psychotics (Lorr, Klett, & McNair, 1963), and college students (Stern, 1970). Within many of these diverse programs of research, the circumplex model has provided a nomological network that has enhanced the meaning and significance of the separate interpersonal variables employed (Schaefer, 1961). Unfortunately, the potential of the circumplex as an integrative conceptual model has not been as widely recognized by those whose research paradigms have focused on the intensive study of single dimensions in personality and social psychology.

In a recent book that presents summaries of research on the major dimensions of personality, the editors state:

> There obviously has been no overarching plan or theory, implicit or explicit, guiding the selection of topics for trait researchers. Indeed, the editors were forced to organize the book by means of the unsophisticated tactic of simply placing the chapters in alphabetical order. (London & Exner, 1978, p. xiv)

But surely the major research topics in contemporary personality and social psychology such as achievement and power (PA), Machiavellianism (BC), aggression (DE), introversion (FG), obedience (HI), interpersonal trust (JK), altruism and helping behavior (LM), affiliation and extraversion (NO)—can be related to each other by schemes more sophisticated than the alphabet. This is not to claim an established isomorphism between the research topics just enumerated and the present interpersonal taxonomy; rather, it is to illustrate the kinds of questions whose answers might bring conceptual clarity to

both taxonomic and experimental research. For example, once it is recognized that the dimensions measured by Bem's (1974) masculinity and femininity scales are the orthogonal interpersonal dimensions of ambitious–dominant (PA) and warm–agreeable (LM), then the issue of the "independence" of masculinity and femininity, so conceived, is seen in a new light (Wiggins & Holzmuller, 1978).

The alphabetical list of human "needs" provided by Henry Murray (1938) has proved to be an exceptionally fertile source of personality dimensions. Within the framework of Murray's personology, several of these dimensions have been studied in considerable depth (e.g., Atkinson, 1958; McClelland, 1961; Winter, 1973), although little attention has been given to the interrelationships among the needs in the overall system, perhaps because an alphabetical taxonomy provides no guidance in this matter. Needs selected from Murray's list have formed the basis for two multiscale inventories (Edwards, 1959; Jackson, 1967) and for scoring keys on an adjective checklist (Gough & Heilbrun, 1965). There appears to be a consistent factor structure associated with the dozen needs these instruments happen to share in common, but attempts to interpret this structure have not been particularly enlightening from a substantive point of view (Huba & Hamilton, 1976). In contrast, the strangely neglected work of Stern (1958, 1970) presents convincing evidence that a circumplex model provides a meaningful representation of the full range of Murray's need variables.

Two-dimensional circumplex models may have utility outside the realm of ordinary language-trait description associated with personality inventories and adjective checklists. The circular ordering of intercorrelations among clinical scales from the MMPI has been noted (Schaefer, 1961), and it has been argued that these scales can be interpreted within a two-dimensional circular model of personality (Kassebaum, Couch, & Slater, 1959). Given the manner in which the MMPI clinical scales were constructed, this argument appears rather farfetched on initial consideration. However, a recent study by Plutchik and Platman (1977) suggests a possible reason why this might be the case. Twelve trait-descriptive adjectives were selected to represent an interpersonal circumplex (Schaefer, 1961). Psychiatrists were then asked to rate seven diagnostic categories (e.g., paranoid, schizoid, hysterical) with respect to these adjectives. The mean adjective profiles of the seven diagnostic categories were intercorrelated, and two factors were extracted. The circular ordering of the diagnostic categories (Plutchik & Platman, 1977, p. 421) bears a striking resemblance to the circular ordering of corresponding MMPI scales reported elsewhere (Schaefer, 1961, p. 135). The constellations of traits implied by diagnostic labels can be represented by a two-dimensional interpersonal circumplex (Schaefer & Plutchik, 1966). To the extent that the MMPI clinical scales reflect conventional diagnostic labeling, they too would be expected to exhibit a circular ordering.

The present taxonomy of interpersonal traits may prove useful to investigators who employ single adjectives as stimulus materials in studies of interpersonal perception, impression formation, and trait attribution. The representativeness of the stimulus materials is always an issue in such studies, and the present taxonomy provides a systematic basis for sampling the entire domain of interpersonal traits as an alternative to, for example, the less differentiated strategy of sampling "favorable" traits. Elaborate sampling procedures for the study of one or more specific dimensions of interpersonal behavior are made possible by the availability of a list of 864 terms that have been classified within 16 categories. The position of an adjective within a given category is indexed by the correlation of that adjective with its own, its opposite, and its orthogonal clusters. In addition, the earlier itemmetric work of Norman (Note 3) provides information on these same adjectives with respect to such characteristics as social desirability, difficulty level, self-endorsement, and attributions to liked, indifferent, and disliked others. Although such itemmetric data are useful primarily for calibration of stimulus materials, they may themselves be profit-

ably studied for the light they shed on basic issues of social perception (Goldberg, 1978).

Self-Awareness, Psychological Perspective, and Self-Reinforcement in Relation to Personal and Social Standards

Ed Diener and Thomas K. Srull
University of Illinois at Urbana-Champaign

The present study was designed to assess whether subjects would be more likely to judge their own behavior from a social perspective when they were self-aware than when they were non-self-aware. Participants reinforced themselves after receiving feedback about a performance task that indicated they had surpassed their own standard, a social standard, both standards, or neither standard. Subjects did not alter their reinforcement as a function of the self-awareness manipulation when they surpassed both standards or neither standard. However, when subjects learned that they had surpassed their own standard but not the social standard, they rewarded themselves significantly more ($p < .01$) and felt more satisfied with their performance ($p < .01$) when they were non-self-aware. When subjects surpassed the social standard but not the personal standard, they reinforced themselves significantly more ($p < .01$) and felt more satisfied ($p < .01$) when self-aware. It was also found that self-awareness decreased feelings of choice in administering self-reinforcement ($p < .001$). The possibility that self-awareness may create a social perspective from which one's own behavior is evaluated and the implications this possibility has for future theory development are discussed.

Duval and Wicklund (1972) outlined a theory of self-awareness that has been extended and refined by Wicklund (1975, in press). The theory maintains that attention may be focused either outward or upon the self as an object. One major emphasis of the theory of self-awareness has been on standard-related behavior. The theory maintains that self-awareness should increase adherence to normative standards, because the self-aware person will be highly aware of any deviations between his or her behavior and these standards. Moreover, since perceived discrepancies between one's behavior and salient standards will cause negative affect, the self-aware person is more likely to avoid antinormative behavior.

Several studies have demonstrated the impact of self-awareness on normative behavior. For example, Diener and Wallbom (1976) found a large reduction in cheating when college student subjects were made self-aware. It has also been found that objective self-awareness increases aggression when subjects think aggression is normative (Carver, 1974), but decreases aggression when they believe it is antinormative (Rule, Nesdale, & Dyck, 1975; Scheier, Fenigstein, & Buss, 1974). The present experiment concerns two ambiguities present in current conceptualizations of self-awareness. The first is whether self-awareness necessarily increases adherence to all types of standards. The second is whether self-awareness produces a purely introspective examination of oneself or whether, under some conditions, self-awareness may create a social perspective from which one's own behavior is evaluated.

The present research was supported by U.S. Public Health Service Grants MH-14257 and MH-15140 to the second author. Appreciation is extended to Fran DeNinno and Dennis Heim for serving as experimenter and assistant, respectively. We also thank Robert Wicklund, Robert S. Wyer, and two anonymous reviewers for their valuable comments on an earlier draft of the manuscript.

Types of Standards

The major purpose of the present study was to explore the question of whether self-awareness increases adherence to all types of norms, only to social norms, or only to personal norms. According to the original theory of objective self-awareness, compliance with both personal and social standards should increase in the state of objective self-awareness. In other words, the theory maintains that *any* salient standard will exert more influence if the person is objectively self-aware, regardless of whether the standard is social or personal. It is possible, however, that self-awareness operates mainly upon one or the other type of standard. Alternatively, Fenigstein, Scheier, and Buss (1975) have identified two types of self-awareness, public and private, and it is possible that adherence to one type of standard will depend on which type of self-awareness is manipulated. It is clear that social and personal standards will often covary to some degree, and no effort has been made in past research to examine their independent effects.

Demonstrations of increased norm adherence have relied mostly on socially imposed standards (cf. Carver, 1974; Scheier et al., 1974). It is difficult, however, to draw any firm conclusions regarding the relative influences of personal and social standards from this literature. In most situations, including those used in past self-awareness research, social and personal standards are undoubtedly intertwined. For example, Carver (1975) found that self-reported belief in punishment led to greater administering of electric shock, but only when participants were self-aware. In contrast, Scheier (1976) found that self-awareness, but not personal attitudes toward punishment, led to heightened aggression among angry subjects. However, these findings do not indicate that social or personal standards were necessarily more powerful or were the locus of the self-awareness effects. Note that in each of the studies mentioned above, personal and social standards were both relevant to the behavior in question. Moreover, the social standard had to be filtered by the subject's perceptions. Thus, based on past research, it is difficult to separate the relative influence of the two types of standards. Even in cases where self-awareness has increased compliance to personal standards, it is quite possible that subjects perceived the social standard to be congruent with their own personal standard. Indeed, there is evidence to show that in the absence of contradictory information, people assume a close relationship between self- and social standards (Ross, Greene, & House, 1977).

Psychological Perspective and Attention to Standards

Another ambiguity associated with past research is suggested by Mead's (1934) self theory, upon which the self-awareness model was originally based. According to Mead, self-awareness is the ability to look at oneself as others do, to adopt an outside social perception of oneself. This suggests that the self-aware person might become more concerned with the opinions of others and more empathic with their viewpoint and therefore conform more to social expectations. On the other hand, the self-aware person might be more aware of personal standards because of self-focused attention and therefore conform more to them. This raises the further question of whether the relative salience of personal and social standards is the same. More specifically, it is possible that the salience of personal and social standards varies dramatically across different situations, and this factor has also been neglected in past research. In the present study, personal and social standards were both made highly explicit and varied independently. This procedure allowed an examination of the relative impact of personal and social standards when they are similar as well as when they are dissimilar.

It is undoubtedly the case that adherence to personal and social standards is not mutually exclusive, and one of the most important immediate problems is to delineate those situations in which the relative impact of one type of standard is greater than the other. By making both standards highly salient, and thereby controlling for differences in attention, the present study is concerned with one such important class of theoretically relevant situations.

In sum, it is suggested that self-awareness has two principal components: attention to aspects of the self and a social perspective of oneself. It is possible that these two components underlie the two individual difference patterns of self-awareness (private and public) identified by Fenigstein et al. (1975). It is hypothesized that when social and personal standards are independently varied, and *attention to standards is held constant*, self-awareness will have a greater impact on adherence to social than personal standards, because of the social perspective subjects have of themselves. The differential reliance on standards was assessed in a self-reinforcement paradigm. Self-reinforcement was adopted because it reflects in a concrete way an individual's evaluation of his or her behavior. In addition, Diener (in press) has recently stressed the interplay between self-awareness and self-reinforcement in developing a theory of deindividuation. Thus, the use of self-reinforcement as a dependent measure provides a potential operational bridge between the theories of self-awareness and deindividuation.

Method

Overview

Participants made a series of 12 perceptual judgments and generated a standard of accuracy within which they would consider an individual's performance to be successful. Later they were given systematically varied bogus feedback concerning their own performance levels, their self-standards of success, and social standards of success ostensibly generated by their peers. Trials on which the subject surpassed both standards, one or the other standard, or neither standard were thereby created. On the basis of the social and self-standards and their own performance levels, participants were allowed to administer reinforcement to themselves under self-aware and non-self-aware conditions.

Participants

Participants were 24 male and 24 female University of Illinois introductory psychology students. Participation in the experiment partially fulfilled a course requirement.

Procedure

Subjects were run in individual sessions. Each participant was greeted by the female experimenter, who introduced her male assistant. Both the experimenter and assistant were blind to the experimental hypothesis. The assistant requested the subject to recite his or her name and hometown into a microphone. This information was recorded on a tape loop for later use.

The subject was told that he or she was participating in the development of a perceptual judgment task. The experimenter explained that she was interested in the maximum performance of which people are capable under actual testing conditions. She stated that there are a variety of distractions, such as the presence of proctors and stray noises, present in testing situations and that concentration is important in determining how well one performs. She explained that there would therefore be a variety of distractions present during the experiment. She stated that as an incentive to perform well, the subject would later be able to reward him- or herself by taking from 0 to 9 "points" on each trial. Furthermore, at the end of the experiment, the total number of points accumulated would be converted to money.

A slide projector was used to provide an example of the perceptual task that subjects would be asked to complete. After displaying a practice slide, the experimenter explained that each of the test slides would contain a large number of dots that would be shown for approximately 4 sec. The subject's task consisted of two parts. First, he or she was to estimate the number of dots on the slide. Second, the subject was told:

> Obviously you will not be able to guess the exact number of dots after seeing the slide for only four seconds. Therefore, I would also like you to tell me within what range you think you should be for it to be a successful performance. That is, within how many dots should your estimate be for you to consider it a success? For example, you might estimate this slide to have, say, 160 dots and think you should be within 25 dots to have a successful estimate.

The subject was then told that he or she would go through a series of test trials. Later, the experimenter would review each trial and report the participant's actual performance level, his or her self-standard for a successful performance, and a social standard of success that was based on the performance of 250 introductory psychology students from the previous semester. The subject would then be able to reward him- or herself for each trial.

After any questions had been answered, the first test slide was presented. With the onset of the first slide, white noise began to filter into the room, ostensibly as the first distractor. Throughout this procedure, the experimenter's assistant could be seen sitting at a desk, recording the subject's responses and performing a number of calculations on a calculator. Although the actual performance of subjects on these tasks was of no import to the study, obtaining the estimates was necessary to make credible the later feedback about their performance and self-standards.

At the end of the 12th slide, the experimenter explained that her assistant had been calculating how well the participant had performed on each trial in terms of percentage of wrong answers. She then took a booklet from her assistant and began reviewing the 12 slides. For each trial, the subject was told his or her own "performance level," his or her stated "self-standard" of success, and the "social standard" of success. These three figures were represented in supposed percentages and shown on a large visual display to facilitate comparison. Obtaining estimates and standards in terms of raw numbers and later representing them as percentages allowed the experimenter to provide the false feedback without suspicion. After receiving the feedback for each trial, the subject took from zero to nine marbles from a container, placed them in an empty bowl as a reward, and told the experimenter how many marbles were taken. The number of marbles taken each time was recorded by the experimenter. The subject then made several short ratings, and the experimenter went on to the next trial.

At the end of the 12th trial, subjects were completely debriefed. Participants were told that the feedback and standards were bogus. The experimenter carefully explained why this was a necessary part of the experiment and said that since she had promised that the marbles would be converted to money, she was paying each participant $2. The experimenter fully discussed any concerns of the subject and was alert to any signs of upset about the deception.

Self-awareness manipulation. Each subject was exposed to both self-aware and non-self-aware manipulations and was led to believe that these were different types of distractors. The self-aware condition was created by having the subject's image displayed on a television screen. It has been shown that seeing one's own image increases self-focused attention (Carver & Scheier, 1978; Geller & Shaver, 1976). In addition, the subject's tape-recorded voice was played on a continuous loop, repeatedly saying, "My name is _____ and I am from _____." Thus, subjects in the self-aware condition were exposed to a voice (ostensibly similar to a person talking) and a televised face (ostensibly similar to a proctor watching them). In the non-self-aware condition, an exciting automobile chase scene was played on the television. The videotape included both picture and sound and was presented as the type of distractor that might occur while a person is studying. The order of the self-aware and non-self-aware conditions was counterbalanced across subjects. Each subject rewarded him- or herself on Trials 1 through 6 while in one condition and on Trials 7 through 12 in the other condition.

Feedback conditions. As noted above, systematic feedback was given to each subject for his or her "performance level," "self-standard" of success, and "social standard" of success. A total of six feedback conditions was created by having the subject's ostensible performance on different trials surpass either (a) both the self- and social standard, (b) the self- but not the social standard, (c) the social but not the self-standard, (d) neither standard, (e) the self-standard, with no information about the social standard, or (f) the social standard, with no information about the subject's previous self-standard. Each subject received the six feedback conditions in a different random order. The feedback was constructed in such a way that the percentage figures given subjects varied considerably from trial to trial in how close they were to the actual number of dots presented, in order to make the feedback more believable. This maneuver seemed reasonable, since some trials appeared very easy, while others appeared very difficult. However, the *discrepancy* between the subject's ostensible performance and either of the two standards was, although not exact, close for each trial. These discrepancies were controlled by making them equivalent when summed over subjects in any given condition.

Self-report measures. A variety of self-report measures were obtained to explore the psychological processes underlying subjects' behavior in self-aware and non-self-aware conditions, to check on the validity of the manipulations, and to check for possible suspicion. After the subject rewarded him- or herself on each trial, two rating scales were completed. One asked, "How satisfied were you with your performance on the last task?" and the other asked, "How much choice did you feel you had in deciding how many points you should take?" At the end of the 6th and 12th trials (i.e., at the end of the self-aware and non-self-aware conditions), subjects were also asked the extent to which they considered their own standards of success and the extent to which they considered the way they might appear to others in rewarding themselves over the previous 6 trials. All of the ratings were made on 11-point scales. The intrusion of additional rating scales after the 6th and 12th trials was not as conspicuous as it might seem, because they occurred at the same time the assistant was changing from one set of "distractors" to another. At the end of the 12 trials, subjects were asked to guess the hypothesis of the study, to say whether they had heard about the experiment beforehand, and to say what thoughts they had about the feedback they received.

Experimental Design

Subjects were exposed to each feedback condition under both self-aware and non-self-aware conditions. The feedback conditions were presented in a different randomized order for each subject. Thus, the experiment was a 2 (sex) × 2 (order of self-aware and non-self-aware conditions) × 2 (self-aware vs. non-self-aware) × 6 (feedback conditions) factorial design with repeated measures on the last two factors.

Table 1
Mean Number of Marbles Taken and Ratings of Personal Satisfaction Under Self-Aware and Non-Self-Aware Conditions as a Function of Type of Feedback

Condition	Surpass self- and social standard	Surpass self- but not social standard	Surpass social but not self- standard	Surpass neither standard	Surpass self- standard only	Surpass social standard only	Total
			Number of marbles				
Own TV image and voice	6.81	3.44	5.75	.88	4.15	6.73	4.63
Chase scene	6.73	5.50	3.65	.98	6.10	4.13	4.51
Total	6.77	4.47	4.70	.93	5.13	5.43	4.57
			Satisfaction				
Own TV image and voice	7.21	3.81	6.27	2.48	5.27	7.50	5.42
Chase scene	7.42	6.00	4.50	2.56	6.65	5.25	5.40
Total	7.31	4.90	5.39	2.52	5.96	6.38	5.41

Note. The possible range of marbles was 0 to 9 (higher numbers indicating greater self-reinforcement), and the possible range of satisfaction ratings was 0 to 10 (higher values indicating greater satisfaction).

Results

The order in which subjects experienced the self-aware (own televised image and own voice) and non-self-aware (televised chase scene) conditions did not produce a significant difference on any of the dependent variables. Sex of subject was significant to the extent that, across conditions, males took more marbles ($M = 4.95$) than females ($M = 4.19$), $F(1, 44) = 9.28$, $p < .01$. The order of the self-awareness manipulation and sex of subject were thus eliminated as variables, and the design was considered a 2 (self-awareness vs. non-self-awareness) × 6 (feedback conditions) within-subjects factorial for all further analyses. It should also be noted that no subject had heard about the experiment beforehand, suspected the feedback was false, or was able to guess the hypothesis of the study. These possibilities were assessed both in the written questionnaire and in verbal interviews.

Self-Administered Reward and Personal Satisfaction

The mean number of marbles taken by subjects in the 12 conditions is presented in Table 1. There was a significant main effect for feedback condition, $F(5, 235) = 167.04$, $p < .001$, and, consistent with the hypothesis, a highly significant interaction between feedback condition and the self-awareness manipulation, $F(5, 235) = 60.62$, $p < .001$. Specific sets of comparisons are particularly germane to the original hypothesis. Those trials in which subjects received feedback indicating that they surpassed their self-standard but not the social standard, or surpassed the social standard but not their self-standard, should indicate the relative weight subjects put on each type of standard in administering reward under self-aware and non-self-aware conditions. Similarly, those trials in which subjects surpassed only the self- or only the social standard will indicate the relative importance of these standards across self-aware and non-self-aware conditions.

Post hoc comparisons using procedures suggested by Tukey (see Keppel, 1973) were therefore computed on selected pairs of means. These comparisons revealed that when subjects surpassed their own but not the social standard, they rewarded themselves significantly more highly in the non-self-aware than in the self-aware condition ($p < .01$). In con-

Table 2
Mean Ratings of Choice Under Self-Aware and Non-Self-Aware Conditions as a Function of Type of Feedback

Condition	Surpass self- and social standard	Surpass self- but not social standard	Surpass social but not self- standard	Surpass neither standard	Surpass self- standard only	Surpass social standard only
Own TV image and voice	6.19	5.29	5.31	4.60	5.42	5.63
Chase scene	7.90	7.60	7.69	7.56	7.73	7.48
Difference	1.71	2.31	2.38	2.96	2.31	1.85

Note. The possible range of ratings was 0 to 10, with higher values indicating a greater feeling of choice.

trast, when subjects surpassed the social but not the self-standard, they rewarded themselves more highly in the self-aware than in the non-self-aware condition ($p < .01$). Further, an identical pattern appears when subjects were only given feedback with respect to one of the standards. Specifically, when subjects surpassed their self-standard but were not told the social standard, they rewarded themselves significantly more highly in the non-self-aware than in the self-aware condition ($p < .01$). However, when subjects surpassed the social standard but were not told their original self-standard, they rewarded themselves more in the self-aware than in the non-self-aware condition ($p < .01$). Finally, it is also important to note that there was no difference in self-reinforcement as a function of self-awareness when subjects surpassed both standards or neither standard.

Subjects were asked how satisfied they were with their performance following the feedback on each trial. It was thought that these ratings would also reflect the relative importance subjects placed on surpassing their own and the social standards in the two conditions. The mean ratings of satisfaction, which are also presented in Table 1, parallel those for self-reinforcement quite closely. There was a main effect for feedback condition, $F(5, 235) = 66.06$, $p < .001$, and a significant interaction between feedback condition and the self-awareness manipulation, $F(5, 235) = 25.95$, $p < .001$.

Post hoc comparisons revealed a pattern identical to that for self-reinforcement. Specifically, subjects rated themselves more satisfied with their performance in the non-self-aware than in the self-aware condition when they surpassed their own but not the social standard ($p < .01$). When they surpassed the social but not their personal standard, however, subjects rated themselves as more satisfied in the self-aware than in the non-self-aware conditions ($p < .01$). Similarly, when subjects surpassed their own standard but did not know the social standard, they rated themselves as more satisfied in the non-self-aware than in the self-aware condition ($p < .01$). However, this finding was again reversed when subjects surpassed the social standard but were not given their original self-standard. Here, subjects rated themselves as more satisfied in the self-aware than in the non-self-aware condition ($p < .01$). Consistent with the hypothesis, there was again no difference as a function of self-awareness when subjects surpassed both standards or neither standard.

One might expect ratings of satisfaction and amount of self-administered reward to be very redundant measures. However, the correlations between these two variables, within each of the conditions, ranged from .13 to .59, with a mean of .41. This result suggests that each of the measures contributed some independent information.

Additional Ratings

Following each trial, subjects rated how much choice they felt they had in deciding how many points to take. The mean ratings of subjects for each of the 12 conditions are presented in Table 2. There was a significant feedback condition main effect, $F(5, 235) =$

2.98, $p < .02$. Examination of the means reveals that, as one would expect, subjects felt that they had the most choice when they surpassed both standards and the least choice when they surpassed neither standard, with intermediate values in the other conditions. More interesting was a strong main effect for the self-awareness manipulation, $F(1, 47) = 50.94$, $p < .001$. Post hoc comparisons indicate that subjects felt that they had more choice when non-self-aware (overall $M = 7.66$) than when self-aware (overall $M = 5.41$) in *every one* of the six feedback conditions (all at least at $p < .05$).

Each subject was asked to make several additional ratings after the 6th and 12th trials (i.e., following the entire block of self-aware and non-self-aware conditions). One question asked to what extent subjects considered their own standards of success in rewarding themselves over the previous 6 trials. Results indicate that subjects considered their own standards of success more in non-self-aware ($M = 7.98$) than in self-aware ($M = 6.13$) conditions, $t(47) = 5.64$, $p < .001$. A second question asked to what extent subjects considered the way they might appear to others in rewarding themselves over the previous six trials. Here, subjects considered the way they might appear to others more in self-aware ($M = 7.77$) than in non-self-aware ($M = 5.25$) conditions, $t(47) = 7.63$, $p < .001$. These data provide a check on the intended manipulation of perspective and add further support to the general contention that subjects see themselves as social objects and are more concerned with social standards when they are made self-aware.

Discussion

Summary of Findings

The major finding of the present study was that subjects relied more on their personal standards of accuracy for evaluating their performance when they were non-self-aware, whereas they relied more on the social standards of accuracy when they were self-aware. Even though the social group from whom the public standard was derived was not present, self-awareness increased reliance upon its standard. Several different measures all pointed to the fact that self-aware subjects were more concerned with their social selves and felt more pressure to comply with the social standard. The self-reinforcement and satisfaction ratings proved to be totally consistent in demonstrating the self-aware person's heavy reliance on social standards. In addition, self-reinforcement was very similar across self-aware conditions in those situations in which subjects surpassed both standards or neither standard. This finding suggests that self-awareness has no effect when both personal and social standards are highly salient and are consistent with each other.

The increased importance of social standards to the self-aware subjects was clearly confirmed in every one of the four conditions in which subjects received feedback that they had surpassed one or another of the standards. In addition, whether subjects received feedback on only one or two standards was unimportant; the social standard produced the large impact on self-aware participants in all conditions. It is important to note that since this was an entirely within-subjects design, these differences represent a dramatic shift in the relative reliance on one standard or the other as a function of the self-aware conditions.

The responses to questions asked at the end of the self-aware and non-self-aware periods confirmed the greater weighting of social standards by self-aware subjects. When asked how concerned they were with their personal standards, non-self-aware subjects reported being significantly more concerned than objectively self-aware subjects. However, when asked about their concern for how they would appear to others, objectively self-aware subjects were the most concerned. Finally, self-aware subjects reported feeling less freedom in choosing their level of self-reward, indicating that they felt less self-directed and more constrained by the situation. Thus, multiple measures across a variety of conditions all demonstrated the objectively self-aware person's greater reliance on social standards. These findings clearly demonstrate that when standards are manipulated in a social situation and attention to the standards is held constant, self-aware persons will heavily weight the social stan-

dard. It would appear that self-aware persons take on a social perspective of themselves in a social situation and judge their performance from this external vantage point.

A close examination of the self-reinforcement and satisfaction data reveals an interesting finding in addition to the clear shift noted above. A number of comparisons all indicate that subjects in one condition or the other weighted a certain standard more heavily, but did not ignore the other standard. That is, all subjects took both standards into account, but simply shifted the relative weight placed on them. When one compares the cells in which only one standard was given with the comparable surpassed-one-but-not-the-other cells, it can be seen that the former are higher for every comparison. This indicates that the standard that was given less weight nevertheless had a definite effect. The fact that the two surpass-both-standard cells have higher values than all others also indicates that one standard was never ignored completely. Thus, self-awareness shifted the weight given the two types of standards, but both standards were always considered.

It is informative to examine more closely the data concerning subjective feelings of choice. In the non-self-aware conditions, subjects felt that they had free choice in determining their reward even when they surpassed neither standard. Thus, even when they gave themselves little reward, they felt that they had a great deal of choice. When self-aware, however, subjects felt much less freedom when they surpassed neither standard. Even more impressive is the fact that self-aware subjects felt that they had less choice in choosing their reward when they surpassed *both* standards than they did in any of the non-self-aware conditions. In fact, the self-aware participants' feelings of choice were highly affected by their performance, whereas this was much less true for non-self-aware subjects. Thus, self-awareness appears not only to decrease feelings of free choice overall but also tends to produce a greater feeling of constraint on the person who has performed poorly. When a person is non-self-aware, he or she appears to feel free in rewarding and punishing him- or herself, suggesting a feeling of internal self-direction.

One interesting finding of the present study was that self-awareness had no impact on self-reinforcement *or* feelings of satisfaction when subjects surpassed both standards or failed by both standards. This indicates that at least when standards are clear and explicit self-aware subjects do not judge themselves more harshly when wrong or reward themselves more liberally when successful. If attention to standards were allowed to vary, however, it is possible that the self-aware person would be more aware of behavior–standard discrepancies and thus reinforce himself or herself differently. Indeed, this is what is typically found in the self-awareness literature (Wicklund, 1975). However, the present data indicate that when attention to standards remains high, self-aware subjects do not judge themselves differently across all types of standards, but simply rely more heavily on the social standard.

Psychological Perspective and Attention to Standards

As noted earlier, one recent line of evidence in the objective self-awareness literature suggests that there are two types of trait self-awareness, private and public (Fenigstein et al., 1975). Private self-awareness is said to be a focus of attention on the covert, internal aspects of oneself, whereas public self-awareness is what is commonly thought of as "self-consciousness"—an awareness of the self as a social object. A person who is privately self-aware should experience a heightened awareness of his or her own beliefs and feelings, whereas a publicly self-aware person should be more aware of his or her social appearance and the impression he or she makes on others. This distinction in the conceptualization of dispositional self-awareness suggests a parallel two-factor approach to the underlying processes involved in state self-awareness—one that emphasizes both perspective and attention. This distinction raises several interesting possibilities that are noted below.

There are several possible explanations for the apparent divergence between the present findings and past results showing greater ad-

herence to personal standards among self-aware subjects. A strong possibility is that personal standards are often adhered to more closely by self-aware subjects because of their close perceived correspondence with social norms (cf. Ross et al., 1977). Another possibility is that self-aware subjects are more aware of both social and personal standards than are non-self-aware subjects, but where the two are clearly discrepant, they weight social standards more heavily than usual because of their social perspective of themselves.

One explanation for the absence of increased adherence to personal standards in the present study concerns the difference pointed out earlier between attention and perspective. In most studies, self-awareness is manipulated, and attention is free to vary, focusing either on aspects of the self or on the environment. Thus, if the typical self-awareness paradigm had been employed, attention would have been free to focus on the external environment or on social or private standards. In such a case, the person might *attend* more to both personal and public standards under self-aware conditions and thus be influenced more by both of them. This interpretation is supported by the findings of Rule et al., (1975), who found that self-aware subjects complied with their own beliefs more when in a situation where no standards had been made explicit.

The procedure used in the present study, however, presented standards in such a way that they were explicit and easily comparable. Thus, attention to the two types of standards was likely to be high in both self-aware and non-self-aware conditions. However, the viewpoint or perspective of the subject was likely to change across the two conditions. The self-aware person was likely to see him- or herself as a social object, and this apparently led subjects to weight the social standard much more heavily. In the non-self-aware condition, subjects were also likely to be equally aware of both types of standards, but here they gave greater weight to the personal standard, apparently because of their egocentric perspective.

This analysis suggests an important distinction between the attention given to different types of standards and psychological perspective in the analysis of self-awareness affects. In order to determine the importance of this distinction, future research will need to examine adherence to the two types of standards when they vary in explicitness, as a function of self-awareness. Since attention to various standards may vary in many situations, a theory explaining which standards will be most salient (and hence most magnified in importance by self-awareness) when standards are not highly explicit is needed. Wicklund (in press) has offered the concept of "end points" (roughly analogous to goals) to explain which standards the self-aware person is likely to attend to, and this approach should be vigorously explored.

Possible Limitations

One factor may limit the generality of the present findings and suggests the need for additional study. It is possible that the present results are due to the fact that subjects did not have a firm basis for their self-standard and thus quickly abandoned it in favor of the social standard when made self-aware. If the person had a strong relevant personal standard, self-awareness might serve to enhance its influence.

Another potential limitation of the present findings is that they may be applicable only to *public* self-awareness (also referred to as self-consciousness). That is, it is possible that the self-awareness manipulation combined with the interaction with the two experimenters induced public self-awareness. Preliminary analyses of a subsequent study in which the self-reinforcement situation was less social in nature indicate that the present pattern of findings may not emerge in a non-social situation. Hence, the findings of increased reliance on social standards may be most applicable to public self-awareness or self-awareness produced in a social situation. Indeed, the process underlying public self-awareness may be the psychological perspective effect varied in the present design. It is interesting to speculate that the effects of private self-awareness depend on attentional differences that were intentionally held constant in the present study.

Future Research

Although it is clear that self-aware subjects relied more upon the social standard, it is also apparent that non-self-aware subjects relied more upon their personal standard. It seems likely that subjects approached the situation with an initial bias toward weighting their personal standard more heavily, possibly because of cultural values related to independence and self-reliance. One possible explanation for the reliance on personal standards in the non-self-aware condition is that the non-self-aware person may have an egocentric orientation that favors personal goals and standards when he or she is aware of them. This possibility deserves further research. The different effects of self-awareness on adherence to performance standards (e.g., those oriented toward reaching a specific goal) and norms (e.g., those used to judge moral or value-related behavior) should also be explored.

Finally, the distinction drawn earlier between the person's perspective or viewpoint and the focus of attention in the self-aware state also provides an intriguing avenue for future investigation. It will be important to examine whether self-aware persons are equally aware of both social and personal standards. If so, it will also be important to determine the precise mechanism through which one type of standard is given more weight than the other. It is possible that *public* self-awareness predisposes one to take the view of others and thus to emphasize social standards. However, *private* self-awareness may focus one's attention on internal factors and thus increase adherence to personal standards. This suggests that the public and private individual difference dimensions may rest on two psychological processes—focusing attention on aspects of the self and taking a social perspective of oneself—that together comprise what has become known as "self-awareness." Moreover, it may be possible to vary these two factors independently. Thus, future research should explore the relation of perspective and attention to public and private self-awareness. One important direction for future theoretical development will be to discover the effects that different types of self-awareness have on adherence to personal and social standards.

Conclusions

The present experiment indicates that self-aware persons may rely more heavily on social standards when judging their performance than non-self-aware persons do. However, the present findings may be limited to variations in social self-awareness. Results also indicated that self-aware subjects felt less freedom in choosing the level of reinforcement for their behavior, suggesting that they felt more constrained by a social perspective of themselves. Focused attention to various aspects of oneself and taking a social perspective of oneself were postulated to be two distinct components of self-awareness. It is suggested that these two components parallel the public and private individual difference dimensions of self-consciousness reported by Fenigstein et al. (1975).

Inferior Performance as a Selective Response to Expectancy: Taking a Dive to Make a Point

Roy F. Baumeister, Joel Cooper, and Bryan A. Skib
Princeton University

An experiment investigated factors that determine whether persons conform to what is expected of them or not. Female subjects took a bogus personality test that established either publicly or privately that they had a particular (fictional) trait, which was presented either as a very desirable or a very undesirable trait. Subjects then attempted an anagram-solving task after being informed that persons with this trait usually perform poorly on such tasks. Subjects for whom the expectancy was presented as derived from the desirable trait, when it was publicly established that they had this trait, solved significantly fewer anagrams than subjects in the other three conditions, implying that self-presentational concerns are important in determining the extent to which an expectancy influences behavior. Moreover, analyses of the differences between the number of anagram solutions subjects reported during the experiment and the number of actually correct solutions suggested that when the expectancy was linked to an undesirable trait, subjects actively sought to disconfirm it.

Past research on expectancies has explored whether expectancies increase the likelihood of the expected behavior (e.g., Rosenthal & Fode, 1963). In particular, studies dealing with task performance have sought to determine whether persons will tend to adjust their performance levels to agree with whatever level they have been led to expect. The main emphasis of this research has been to determine whether the subject's cognitions of task and expectancy seem to generate some internal processes (such as drives toward cognitive consistency) that induce him or her to perform at the expected level. Thus, Aronson and Carlsmith (1962) proposed that if one expects poor performance, one will avoid good performance because the latter would cause "cognitive dissonance" (Festinger, 1957). Subsequent research, however, has not consistently found this "rejection of success" nor established what cognitions or situational factors produce it (Brock, Edelman, Edwards, & Schuck, 1965; Cottrell, 1965; Lowin & Epstein, 1965; Marecek & Mettee, 1972; Mettee, 1971; Ward & Sandvold, 1963).

Archibald (1974) reviewed the literature dealing with such "self-fulfilling prophecies," that is, with events that tend to occur *because* someone expects them. Archibald raised several unresolved questions regarding the nature of such expectancy effects and closed with a vigorous call for further research. Specifically, he proposed several possible internal cognitive dynamics (such as dissonance, anxiety, and defensiveness) that might account for the self-fulfilling prophecy effects.

The present investigation was motivated by our contention that the effects of an expectancy on behavior are *not* necessarily or exclusively a product of the internal dynamics of the individual—especially when the expectancy originates (as it usually does) outside the individual. Rather, the desire to convey a particular impression of oneself to others in the situation may in some cases be a more important determinant of the individual's response to an expectancy than the individual's private drives toward maintaining a certain self-concept or achieving cogni-

tive equilibrium (Tedeschi, Schlenker, & Bonoma, 1971).

The Public Context: Self-Presentation

It is generally assumed that persons try to maintain favorable evaluations of themselves and that one basic criterion of self-esteem is how successfully a person feels he or she has managed to live up to an "ideal self" (e.g., Cohen, 1959). Separate from one's desire to *be* the ideal self, however, is a motivation to convince others that one's personality resembles one's ideal self. Schlenker (1975) has provided evidence that the motivation to present a highly favorable image of oneself is *not* dependent on having such a favorable self-image. Our point is that behavior in response to expectancies furnished by others [1] is more likely to be motivated by the latter (communicative or self-presentational) interest than by internal goals of protecting one's self-esteem or achieving cognitive balance.

Our investigation therefore emphasized the effect of the context of an expectancy rather than a self-fulfilling effect of the expectancy itself. Depending on the context, the same expectancy could conceivably elicit different behaviors. This brings up the distinction between the *content* and the *basis* of an expectancy. The content is what the target person is expected to do. The basis is whatever attributional reasoning led to the formation of the expectancy. For example, if a man is believed to be a lazy person, one might expect him to spend his spare time watching television rather than playing tennis. The content of this expectancy is the behavioral preference for watching television; the basis is his laziness.

It is plausible that the target's response to an expectancy will depend not only on how he evaluates the expected behavior but also on how he feels about the supposedly underlying trait that is attributed to him. One reason for a target person's sensitivity to the observer's *basis* for expectancy may be that it changes the significance of the target's eventual behavior. The target person must take into account that for him to conform to the behavioral expectancy will confirm the observer's attribution to him of the supposedly underlying trait. Even if the target person believes there is no relation between the trait and the behavior, even if he would deny that he has that trait, he must acknowledge that the observer will interpret the expected behavior in relation to the attributed trait. After all, if the target person (for whatever reason) behaves consistently with the observer's expectancy, the observer will in all probability feel simply that the hypothesis has been confirmed.

Predictions

The present experiment was designed to investigate whether differences in responses to a given expectancy as a function of its context are due to public, self-presentational concerns or to private, internal motivations. Our subjects were informed that they were expected to perform poorly based on a trait they (supposedly) had, which was presented either as a desirable or an undesirable trait. Half our subjects were led to believe that they alone knew that they had the underlying trait and were therefore expected to do poorly, the remainder of the subjects were identified publicly as having the (good or bad) trait that predicted poor performance. We predicted that the expectancy would successfully elicit poor performance only when the expectancy was public and only when it was publicly linked to the desirable trait. However, a viewpoint based on the belief in the internal dynamics of the individual as the essential or exclusive mediators of expectancy effects would predict that the results would be the same in the public as in the private treatment conditions.

Relation to Past Work

Although previous research has largely ignored the issue of how responses to expectancies are determined by the public or private

[1] We are not dealing with expectancies that originate within the actor. Such expectancies may well operate independently of public or self-presentational interests.

nature of their contexts, various findings can be interpreted as suggesting a connection between self-presentational concerns and the beliefs and expectancies of others. For example, Zanna and Pack (1975) found that women will present themselves consistently with the sex role attitudes of an attractive male. Similarly, Deutsch and Gerard (1955) demonstrated that conformity to an obviously false majority judgment is greatly reduced if subjects express their judgments anonymously.

A study by Sigall, Aronson, and Van Hoose (1970) is relevant to the present discussion. Their subjects copied lists of telephone numbers after being told that they were expected to perform at a level either below or above that of the subjects' own "practice round" level. In a third condition, subjects were given the expectancy of performance lower than their own *and* told that subjects who performed well on this task had obsessive-compulsive personalities. Sigall et al. found that this third condition produced poorer performance (i.e., fewer numbers copied) than a no-expectancy control condition, whereas the first two conditions elicited superior performance.

However, Sigall et al. were primarily interested in a methodological issue, and their results (although suggestive) do not provide conclusive evidence about reactions to expectancies. In the first place, subjects performed better than controls after an expected level of performance was communicated to them. But it made no difference whether this expected performance level was set above *or* below the subject's pretest level. Both produced improved performance. Sigall et al. suggest the possibility that subjects did not perceive the expectancy in relation to their pretest performances. Therefore, they may not have known whether an increase or a decrease was expected.

In fact, Sigall et al. (1970) reported a second experiment in which the expectancy manipulation was omitted altogether, and improved performance was found as a result of simply telling the subject more about the study (and informing the subject that a hypothesis existed, without telling the subject what it might be). These results therefore seem to imply only that experimental subjects work harder if the experimenter makes a greater effort to explain the purpose and direction of the research than if the experimenter simply tells them what to do. Although this is an interesting finding, it does not have a direct bearing on how persons are affected by what others expect them to do.

The results of the obsessive-compulsive treatment also can be understood without reference to the expectancy about the subject's performance level. Subjects were told that only obsessive-compulsive personalities performed well on that task. The task was thus presented as the only indication of whether the subject was an obsessive-compulsive. Rather than presenting the subject with an expectancy based on an already made inference about his or her personality, the subject was presented with this task as a means of determining whether the subject was an obsessive-compulsive or not.

Thus, although the procedures and results of Sigall et al. raise a number of issues germane to the present investigation, they cannot be considered to provide clear or definitive answers to these questions. Of course, the most important difference between the procedures of Sigall et al. and ours is that their work provides no indication as to whether any such motivation toward inferior performance derives essentially from a private desire of the individual to protect self-esteem or from self-presentational interests. The present investigation was directly concerned with this issue.

Method

Subjects

Forty-one undergraduate women volunteered for a study on "personality and behavior." Data from one subject were discarded because she inadvertently undermined a manipulation by announcing her pretest results aloud when they were supposed to be known only to her.

Subjects participated in the study individually, although a male confederate, who pretended to be another subject, was present for all sessions. All subjects were offered and paid $2.50 for their participation. They were assigned at random among the four treatment conditions.

Female subjects were used exclusively because of availability and to ensure a reasonably homogeneous sample. The cover story and operations were adapted so as to be suitable for an exclusively female sample.

Procedure

Pretest. When the subject arrived at the experimental room, the male confederate was not yet present. The female experimenter[2] said that the first procedure involved a personality inventory that was designed for the female subjects. Since the other participant scheduled for that session was male, the present subject might as well begin the personality measure without waiting for him to arrive.

The pretest was in fact bogus. Its only function was to provide a vehicle for convincing the subject that she scored high on the bogus personality trait from which the behavioral expectancy would later be derived.

In order to facilitate the confidentiality of the subject's score and in order to avoid suspicion concerning the results of the test, subjects scored their own tests. The tests were structured so that all subjects would score high on the trait in question.

The male confederate waited until the female subject was nearly finished taking her test. He entered with a confused apology for being late. The experimenter instructed him to sit across a large table from the subject. A large barrier precluded visual contact.

Manipulation of trait desirability. The subject heard one of two tape-recorded briefings. Both began by informing subjects that the preceding personality test was a measure of the trait of "surgency." Our use of the term *surgency* followed Ickes, Wicklund, and Ferris (1973), who suggested that the term is well suited to denote a bogus personality trait because it sounds like authentic psychological jargon but does not have a meaning that is familiar to most subjects.

Both initial briefings stated that it was expected that many Princeton women would be high in surgency because of their unusual developmental backgrounds. The importance of the research on surgency was stressed. Moreover, the recorded voice said that even if the subject did not score high on surgency, her participation was valuable in order to furnish a comparison with the high-surgency group. In addition, a male control group was to be included.

There followed the explication of surgency. In the "good" condition, the recording protrayed high-surgency women as unusually mature and well-adjusted, sensitive, intelligent, and insightful. A speculative developmental scenario suggested that the introduction of some aspects of traditionally male socialization resulted in an optimal "best of both worlds" personality development in the high-surgency woman.

In the "bad" condition, high-surgency women were depicted as immature and ill-adjusted, shallow, insensitive, defensive, and insecure. The implication of the developmental argument was that exposing the young female to some aspects of traditionally male socialization made her insecure about her femininity.

Manipulation of public/private. At this point, the subject was asked to score her own answer sheet for surgency. She was given a scoring template and a red pen and instructed to mark it. In the "public" condition, the experimenter asked the subject aloud what her score was, stated publicly, "That is above 13, so you are 'high' in surgency," and made a show of recording the subject's name, score, and "high" in a data record book. Although the confederate made no comment, it was obvious that he heard all the proceedings. The experimenter then collected the subject's answer sheet, after making certain that the subject had written her name on it.

In the "private" condition, the subject was instructed not to write her name on the answer sheet (or on any of the experimental materials). She was assigned an arbitrary three-digit "subject number" by which her data would later be assembled. When it was time for her to score her answer sheet, the experimenter gave her the template and explained how to score it and how to determine if she was in the high-surgency group. The experimenter then left the subject alone to do the scoring and recording, after saying that she (the experimenter) was not supposed to know the subject's score. When the subject was finished, she folded her answer sheet and stuffed it into a box full of other answer sheets, closed the data book, and returned the materials to the experimenter.

The criterion "13 high/12 low" was written on the blackboard and was thus apparent to all subjects, although until they scored the tests it presumably had no significance for them.

Anagram task. The tape-recorded instructions announced that the next procedure would involve solving anagrams. A brief statement of the rationale for including this measure in the experiment contained the critical prediction that high-surgency women were expected to perform poorly on the anagram task.

In the "good" condition, it was explained that anagram solving is a simple, mechanistic cognitive task and that because the talents of the high-surgency woman are geared toward tasks involving meaning, creative tasks, and tasks involving insight into and understanding of other persons, she would not perform well on exercises like anagram solving. In the "bad" condition, it was asserted that the defensive vigilance of the high-surgency woman makes her reluctant to immerse herself in a simple, mechanistic cognitive task, because she prefers to keep her attention on interpersonal matters "where the source of her insecurities lies."

---

[2] The authors wish to thank Elaine Seligman for her very capable performance as the experimenter.

Table 1
Mean Number of Anagrams Reported and Actually Solved

Condition	Trait	
	Bad	Good
Private		
Reported	21.5	23.2
Actual	20.3	22.8
Public		
Reported	22.7	14.4
Actual	21.8	14.3

Note. $n = 10$ per cell; maximum possible number of anagrams = 40.

Following the prediction of poor performance among high-surgency women, the tape recording said that performance among low-surgency women was "considerably less uniform." Low-surgency women might therefore do well or poorly. Specific instructions for the task were then given: It would involve two 8-minute sessions, each with a list of 20 anagrams; all sets of letters could be unscrambled to make English words (this was true); the subject should solve as many as possible in the alloted time.

Anagram performance was to be public for all subjects. The initial instructions said that after each list, the experimenter would ask each subject how many anagrams he or she had solved. Following the first list, the experimenter asked first the subject and then the confederate how many anagrams (out of 20) they had solved. The confederate invariably reported the same number as the subject had. Following the second list, this was repeated, except that the confederate reported having solved two fewer than the subject. The number of anagrams solved by the subject was the main dependent measure.

Finally, a postexperimental questionnaire contained manipulation checks and solicited reactions to or feelings about the procedures. A careful debriefing followed in which the nature and necessity of all deceptions were fully explained.

Results

Manipulation Checks

An item on the postexperimental questionnaire asked subjects to "Indicate how you felt about the results of the personality test." Four subjects left this item blank. Subjects in the desirable trait condition felt much better about having high surgency than did subjects for whom surgency was presented as an undesirable trait, $F(1, 32) = 6.84$, $p < .02$. Neither the effect for the public/private variable ($F < 1$) nor the interaction ($F = 1.66$) approached significance. A second item asked whether the other subject (i.e., the confederate) had been aware of the results of the subject's personality test. The appropriate answer would of course be "yes" for the public conditions and "no" for the private conditions. All but three subjects answered this item correctly. We did not discard the data from these subjects. However, omission of their data would not reduce the significance levels of the analyses.

Anagram Solutions

The experimenter recorded how many anagrams the subjects reported having solved. Another experimenter later scored all the problem sheets for the actual number of correct solutions. Because there were occasional discrepancies between the number of anagrams actually solved and the number reported aloud, separate analyses were performed on these two measures.

Mean anagram scores for both reported and actual solutions are presented in Table 1. Both analyses of variance revealed significant interactions between the two independent variables: for reported scores, $F(1, 36) = 8.00$, $p < .01$; for actual scores, $F(1, 36) = 7.86$, $p < .01$. In addition, the main effect for public–private was significant, $F(1, 36) = 4.62$, $p < .05$, for the reported scores, but not for the actual scores. It is clear from Table 1, however, that the significant effects are attributable to the disparity between the performance of the good trait/public group and the other three conditions. Using Tukey's honestly significant difference (HSD; see Kirk, 1968) technique, the good trait/public cell mean was found to be significantly lower than each of the other means for the reported scores ($p < .05$) and lower than each of the others except the bad trait/private cell mean for the actual scores. The difference between the good trait/public and the bad trait/private cell means for the actual scores was, however, significant ($p < .05$) according to Fisher's LSD (least significant difference) technique. No other pairwise difference between means was significant. It seems, thus,

that the good trait/public treatment was much more effective then the others in eliciting behavior consistent with the expectancy.

Discrepancy Between Reported Score and Actual Score

Some subjects reported scores that were different from the actual number of anagrams they had solved correctly. When this difference occurred, the reported scores were invariably greater than the actual correct scores, implying that these were not simply random, honest mistakes. We shall use the term *enhancing* to refer to a subject's reporting a score greater than the correct one. A measure of enhacing was obtained by subtracting the actual number of anagrams each subject solved correctly from the number she reported during the experiment. Analysis of variance on these enhancing scores revealed only one significant effect, and that was the main effect for the desirability of the trait, $F(1, 36) = 6.44$, $p < .02$. Subjects in the bad trait conditions enhanced significantly more than subjects in the good trait conditions.

That this difference was a general trend and not due to a few isolated individuals can be verified by considering the number of subjects who enhanced. Only 2 of the 20 subjects in the good trait conditions enhanced. In the bad trait conditions, however, 12 of the 20 subjects enhanced. The chi-square analysis of this difference is highly significant, $\chi^2(1) = 10.99$, $p < .001$.

Difference Between the Two Anagram Lists

Subjects worked two lists (labeled A and B) of anagrams. All subjects did List A first. The difference between the performance levels on the two lists was not influenced systematically by the independent variables.

However, the patterns of enhancing on the two lists *did* vary among the different conditions. For each subject, the difference between her enhacing on the first (A) test and on the second (B) test was obtained by subtracting the enhancing score (reported minus actual anagram solutions) on the B list from that on the A list. Analysis of variance on these differences showed only one significant effect: an interaction between the public–private and the good–bad trait variables, $F(1, 36) = 4.53$, $p < .05$. Because enhancing was negligible in the good trait conditions, the interaction arises chiefly from the bad trait cells. The bad trait/private condition subjects enhanced more on the A list than on the B list, whereas the bad trait/public condition subjects enhanced more on the B list than on the A list. The difference between the bad trait/private and the bad trait/ public means on this measure is significant ($p < .05$) according to Tukey's HSD technique.

Final Questionnaire

Several questions on the postexperimental questionnaire asked subjects to rate on 5-point scales how hard they had tried to do well on the anagram task and how hard they had tried to conform to the level of performance that was expected of them. No significant differences were found on these measures.

Discussion

Experimental subjects typically perform tasks to do the best of their ability, motivated presumably by implicit demand characteristics, habit, and concern with self-esteem and public esteem. Our subjects systematically violated this practice and performed at a level significantly below that of their capabilities when they were publicly expected to do poorly and this expectation reflected a desirable quality in their personalities.

There is no evidence from our self-report (or other) data of any conscious intention to achieve inferior performance. Still, it seems apparent that a person is at some level sensitive to how others will interpret her behavior and that she will modify her performance level in order to convey the desired message. Because the inferior performance levels were found when the expectation about the subject was public but not when it was private, it is clear that the public nature of the expectation was indispensable in eliciting conformity. We interpret this result as meaning that

modification of performance level was due to essentially communicative interests. It has been shown previously that the presence or orientation of an audience can raise concerns that may interfere with performance (Brown, 1968, 1970; Brown & Garland, 1971; Cottrell, Wack, Sekerak, & Rittle, 1968; Deutsch & Gerard, 1955; Henchy & Glass, 1968). In the present study, the performance was reduced to a mere tool for the communication of information that had no analytical relation to the task itself. We submit that the concerns raised by the audience expectancies in the present study were not merely distractions that interfered by competing with the task for the subject's attention (for such concerns would have been equally if not more potent in the public expectancy/*bad* trait condition) but actually preempted the desire to do well.

Illicit Enhancement

Illicit performance enhancement did seem to reflect some internal motivation, in that it occurred in both the public and the private versions of the situation in which the expectancy of poor performance was linked to an undesirable (bad) trait. When poor performance was expected on the basis of an undesirable trait, our subjects were eager to do well. Although they performed no better than subjects in the private expectancy/good trait condition, they resorted more to illicit techniques such as reporting nonwords as solutions and simply miscalculating their score in their favor. This suggests that they were strongly motivated to achieve high scores, possibly in order to discredit the attribution of the bad trait to them by disconfirming the prediction based on it.

An alterative interpretation of this finding can be derived from the work of Aronson and Mettee (1968). These authors found that subjects were more willing to engage in dishonest behavior after receiving an unfavorable evaluation than after receiving a favorable one. By cheating at a game, subjects could demonstrate that they apparently had extrasensory perception (ESP), a possibly very desirable trait that had not been mentioned in the unfavorable evaluation. The cheating of these subjects may therefore have represented a self-enhancement designed to compensate for the bad evaluation (Baumeister & Jones, 1978). It is possible that if one knows that one is evaluated unfavorably by others, this knowledge effectively reduces the inhibitions against using illicit means in order to look good. The illicit performance enhancement of our subjects following the bad trait treatment can be seen as an instance of this possibility.

Moreover, there was a difference in the patterns of illicit performance enhancement between the public and the private versions of the condition in which the expectancy was based on an undesirable trait. When the expectancy was private, subjects resorted to illicit enhancement more on the *first* of the two anagram tasks, but when it was public, they did so more on the *second* test. The only difference in the situation between the two tests was that after the first test, the subject and the confederate reported a score equal to that of the subject. Thus, if the subject enhanced her performance on the first list and not on the second list, she was apparently content with performing just as well as the confederate; whereas if the subject enhanced her score more on the second test, she was apparently not content with matching the confederate but wanted to do better than he.

We did not predict this finding, but we venture a post hoc speculative interpretation. In the private condition, the subject's internal desire to discredit the notion that she had high surgency was satisfied by doing as well as the confederate. In the public condition, however, she had the additional concern of discrediting the attribution (of high surgency to her) in the eyes of the others present, and she could not assume that they would be as easily convinced as she herself might be. In other words, she could not be certain that the others would consider the expectancy of poor performance disconfirmed if she merely performed at the same level as the confederate; therefore, after learning that her score on the first test equaled his, she was tempted to resort to illicit enhancement on the second test in the hope of exceeding his score.

Subjects in the private expectancy/good trait condition showed no sign of trying either to raise or to lower their performance level from the level appropriate to their ability. There is no reason to infer that they endowed the task with any surplus meaning. That is, there is no evidence that they believed poor anagram performance would convince the audience that they had high surgency. In this respect they were unlike the subjects in the other three conditions.

Origin of Expectancy

A possible boundary condition of the present findings is implied by the fact that the subject herself provided the basis for the expectancy by her own behavior (that is, the expectancy was based on her test responses). The findings of Gurwitz and Topol (1978), although not based on behavioral measures, suggest a relation between whether a person has given evidence in support of an expectancy and how the person will subsequently intend to behave vis-à-vis that expectancy.

Because our subjects were women, our findings might be considered in the context of literature that has suggested that women perform below the level of their abilities because of a "fear of success" (Horner, 1972). Our study was not designed to address this issue. Still, it might be noted that in our sample, any motivation to perform below the level of one's ability was derived from immediate *public* expectancies and self-presentational interests rather than from internalized stereotypes or dispositional fears of success.

Conclusions

The present findings do *not* mean simply that women perform poorly when bad performance means something good. Rather, our evidence indicates that an expectancy exerts effective power over a woman [3] toward eliciting behavior confirming the expectancy *if* the following two conditions are satisfied: The expectancy is based on a desirable rather than an undesirable aspect of the target's personality, and other persons present in the situation are aware that this trait (on which the expectancy is based) is attributed to the target person. We do not deny that internal expectancies can affect behavior. Nonetheless, our findings imply that in order to understand responses to overt public expectancies, one must take into account not only the internal cognitive dynamics of the individual but also the individual's self-presentational interests. The influence of expectancy on behavior is in part determined by the expectancy's derivation and context, which give extra meaning to the behavior in the face of the expectancy and which therefore affect the self-presentational strategy.

---

[3] Our conclusions are stated in reference to women because our experimental sample consisted of women. We do not, however, wish to imply that our hypotheses would not be true for men.

Sex Differences in the Allocation of Pay

Charlene M. Callahan-Levy
New College, University of South Florida

Lawrence A. Messé
Michigan State University

The present research examined the possibility that relative to males, females perceive less of a connection between their work and monetary rewards. In Study 1, females and males determined either their own pay or the pay of another person. The results supported the hypothesis, in that (a) females paid themselves less than did males, and (b) females paid themselves less than other people (males or females) paid females. Moreover, the results suggested that subjects were more generous when they paid females. In Study 2, sex differences in self-pay were examined in samples of first-, fourth-, seventh-, and 10th-grade subjects. Results replicated those of Study 1, in that at every grade level, females paid themselves less than did males. In addition, the extent to which females allocated pay the way their male counterparts did was found to be highly related to the masculinity of their career goals. Some implications of these results for the understanding of inequitable consequences of traditional sex roles are discussed.

One of the more consistent findings generated by studies of reward allocation behavior is that American female allocators pay themselves less than do males (Lane & Messé, 1971; Leventhal & Lane, 1970; Mikula, 1974; Messé & Lichtman, Note 1). While this sex difference has been demonstrated a number of times, there have been few empirical investigations of the numerous speculations that have been offered to account for this phenomenon (e.g., Leventhal, Note 2). Thus, the present research examined one possible explanation, derived from the position of Mednick and Tangri (1972) and Chesler and Goodman (1976), that relative to males, females perceive that money is less salient a reward for the work that they perform.

Mednick and Tangri (1972) and Chesler and Goodman (1976) speculated that females learn that performances of the sex role-related tasks traditionally assigned to them (e.g., mothering, housekeeping, etc.) usually are not rewarded monetarily in any direct way. It is possible that the lack of a relationship between money and the traditional tasks for women generalizes to some extent to other work situations as well. Moreover, this perception may be reinforced indirectly by sociocultural biases about females' relative "needs" for monetary rewards. For example, differences in pay as a function of sex often have been "justified" by assertions that it is acceptable for women to earn less than men because women usually do not provide the sole means of economic support for their families. Males, on the other hand, might learn to distinguish between family-oriented tasks, for which no money is expected, and "work," which they perform for pay.

Males also may come to see money not only as a means to acquire goods and services but also as a symbol of how their work is evaluated and, thus, as a measure of their worth. Females, however, may not perceive

This research was supported by National Institute of Mental Health Grant MH24550, "Sex Differences in the Distribution of Rewards," and the Computer Institute for Social Science Research, Michigan State University. Study 2 was a modification of the first author's doctoral dissertation, submitted to the psychology department at Michigan State University. The authors are grateful to Michael Albrecht, Larry Bozyk, Sharon Daugharty, Larry Hall, Cheryl Isaac, Dave Kritt, Deborah Levine, John MacFarlane, Sandy Pritchard, and Deborah Shulman for their assistance in data collection.

their pay to have this evaluative component, since the traditional tasks at which women are "supposed to do well" and to which their self-concepts are supposed to be tied (e.g., mothering, cleaning, cooking, etc.) are not "jobs" for which pay is expected. Chesler and Goodman (1976) speculate that women might use money as an index of self-worth to the extent that they can acquire it without working for it in the traditional sense, that is, when it is "magic money."

Given that females might have internalized less of a connection between work and pay and between pay and self-esteem, it follows that females' views of money as pay would be influenced by a number of factors that males would perceive as less relevant. For example, females could be concerned with appearing "nice," "not greedy," or "not concerned with money," and so forth, whereas males could be concerned almost entirely with getting paid at least what they deserve.

This article reports two studies that examined the implications of this argument. In Study 1, we explored the extent to which sex differences in reward distribution found in past studies were due, at least in part, to the tendency of females to pay themselves less than males pay themselves. In Study 2, we attempted to replicate some of the major findings of Study 1 and to extend them by examining self-pay allocation in other subject populations and by relating this behavior more directly to sex role socialization.

Study 1

The "less-of-a-connection" hypothesis can be viewed within the perspective of equity theory (Berkowitz & Walster, 1976). In one version of the theory (e.g., Lane & Messé, 1972; Weick, 1966), persons are assumed to have, among other criteria of equity, an internal standard by which they judge the adequacy of the compensation that is available for a given level of work inputs. This standard can be applied both to one's own rewards ("own equity") and the rewards of other persons ("other equity"). It could be that males are at least as likely to apply this internal standard of fair pay to outcomes that are potentially available for their own inputs as they are to apply it to the potential outcomes of others. Females, on the other hand, could be more likely to apply the internal standard to the outcomes of others than they are to their own outcomes. In Weick's (1966) terms, the more tenuous connection between work and pay that is hypothesized to be found in females could be manifested in a weaker sense of own equity. Further, as discussed above, this hypothesized weaker sense of own equity would make females more susceptible to the influence of such factors as concerns with impression management, which would tend to affect adversely their judgment about what is appropriate pay for themselves.

An alternative interpretation, again cast within the framework of equity theory, is that persons, both males and females, apply different standards of fairness to the pay of females and males. Thus, it could be that both males and females believe that women should be paid less than men for a given amount of work. This difference in the perception of what is fair pay would mean that the "double standard" of different pay for the same work by males and females would have the status of a general norm.

Both explanations involve a sex difference in the connection between work and pay, and both would account, at least in part, for the reward allocation findings of past research. In these studies (e.g., Leventhal & Lane, 1970; Mikula, 1974; Messé & Lichtman, Note 1), allocators typically were asked to divide anonymously a monetary reward between themselves and another person. In this zero-sum situation, it could be that females gave the other person more in part because they conformed to a norm that specified that women (including themselves) deserved less. On the other hand, it also could be that the female subjects in these studies allocated relatively more reward to the other person in part because they might have perceived less of a connection between their own work and the money that they could give themselves, and thus, they could have been more susceptible to being influenced by concerns with the other person's welfare, by the norm of equality, and so forth.

However, the procedure that typically was used in these past studies—where subjects divided a reward between themselves and another person—does not separate the impact on allocation behavior of people's internal standards from the impact of their interpersonal concerns. The present study, on the other hand, used a procedure that reduced the salience of interpersonal concerns and thereby permitted a more direct exploration of the hypothesis that females perceive less money as an appropriate reward for themselves than do males. In addition, it also permitted a direct examination of the extent to which the tendency in females to pay themselves less is a result of a weaker sense of their own equity or of a general norm that persons apply to all women.

In the present research, female and male subjects were asked to pay either themselves *or* another female or male for a given period of work. If females do, in fact, perceive less of a connection between work and money and, as a result, are more influenced by additional concerns, they should pay themselves less than do males. Moreover, given that the hypothesized less-of-a-connection is reflected in a weaker sense of own equity, then females should pay themselves less than both females and males pay other females. However, if the sex difference in reward allocation is based on a general norm, then females should pay themselves less, and both females and males should pay females less than they pay males.

Method

Subjects and Recruitment

One hundred twenty-six undergraduates, 66 females and 60 males, served as subjects in this experiment. These persons were chosen by chance from approximately 400 respondents to an advertisement in the Michigan State University student newspaper that solicited subjects for pay.

Design

Three dichotomous independent variables were examined via a factorial design. The variables were (a) the target of the allocation (the allocator or another person), (b) the sex of the target person, and (c) (included as a control to complete the design) the sex of the nontarget person (same as or different from the target). When the subject was choosing pay for herself (himself), the sex of the nontarget merely referred to the sex of the people in the other group (see below). When the subject was paying the other person, the sex of the nontarget referred to the sex of the allocator. Viewed from a simpler, more straightforward perspective, the design involved the sex of the allocator, the sex of the people in the other group, and the target of the allocation (the allocator or a person in the other group). However, the comparisons of greatest interest, which were subsumed under the Target × Sex of Target interaction, could be examined most directly when the design was cast in the more complicated format.

Procedure

Subjects were examined in 16 groups of six or eight persons.[1] Four of the groups were composed entirely of females, four entirely of males, and the remainder were composed so that half of the participants were male and half were female. In two same-sex groups and four mixed-sex groups, each subject allocated money only to herself (himself) after she (he) had completed a pretask; in the remaining groups, half the subjects each allocated pay to another person, who also had completed the pretask but who did not allocate payment.

When subjects arrived for the experiment, they were divided between two large tables in a rather spacious room. In mixed-sex groups, females were always assigned to one table and males to the other. Two experimenters, one male and one female, handed out the pretask materials and explained what the subjects were to do. They always started by explaining that the subjects were participating in a study that attempted to simulate an industrial setting. This rationale has been used a number of times in past reward distribution studies (e.g., Leventhal & Michaels, 1969).

The pretask consisted of a number of essay questions pertaining to relevant campus-related issues.[2] Subjects were asked to spend approximately 5 minutes writing their own opinions on each question or topic. It was stressed that this task was nonevaluative, in the sense that there were no right or wrong answers to the questions.

---

[1] It should be noted that a group of subjects performed only the initial task in the same room. As explained in detail below, subjects always allocated pay and completed the postallocation questionnaire in separate cubicles.

[2] This task appears to be an appropriate choice for a nonevaluative work input, given that 223 males and females, when asked to work on and evaluate it, generated no sex differences in their perception of their absolute or relative enjoyment, skill, effort, and quality of performance; multivariate $F(8, 214) = .90$, $p < .5$.

At the end of 50 minutes, the experimenters collected the finished questionnaires; then they told the subjects that the remainder of the session would be devoted to paying them. In the self-allocation conditions, each subject was led to a cubicle, where she or he was given $6 in bills and change, two envelopes—one marked "My pay" and the other "Remainder"—and a short questionnaire that asked (a) the amount of money allocated, (b) the reason, in the subject's own words, why this amount was chosen, (c) the amount of money (up to $6) that the subject thought would be fair pay for this work, and (d) the sex of the person in the "other group." The experimenter explained that each subject should pay herself (himself) any amount, up to the maximum of $6, by placing the desired amount in the "My pay" envelope. This amount was hers (his) to keep. The subject was to take the remainder and place it in the appropriately marked second envelope. He (she) was informed that the amount that was left over would be returned to the general research fund, and thus, his (her) allocation would not affect the payment of any other person. After allocating the money, she (he) was then to complete the questionnaire, fold it, place it in the "Remainder" envelope, seal the envelope, and deposit it in a box that was placed at the exit to the room.

In the other-allocation conditions, only half the subjects (always sitting at the same table) were led to the cubicles, while the remainder stayed at their original places at their table. Once in the cubicles, subjects were told that they were to allocate up to $6 to pay one of the other subjects who was left in the original room. The specific person who would be the recipient of the allocation was to be selected by chance, and her (his) identity would never be disclosed to the allocator, nor vice versa. (However, in a matter-of-fact manner the experimenter stated verbally, and the written instructions indicated, whether the recipient was female or male.) Again, each subject in the cubicles was handed two envelopes—this time, however, one was marked "Her (or His) pay" and the other was marked "Remainder"—and a similar short questionnaire. The experimenter stressed that the allocator's behavior in no way influenced his or her own pay, which had been determined in advance but would not be revealed or dispensed until this task was completed. The procedure for allocating pay to the other person was essentially the same as that used in the self-pay conditions, except that the allocator placed both envelopes in the box before she (he) was given a sealed envelope containing $2.50. The experimenter did, in fact, take the pay envelopes and distribute them at random to the subjects who were waiting in the original room.

Results

There were two payment scores obtained from each allocator. One score was the amount of money that subjects (on the postallocation questionnaire) reported giving to the target of the allocation; the other was the amount of money that the allocator indicated was "fair" pay.[3] These scores were subjected to separate 2 (target: allocator or another person) × 2 (sex of target) × 2 (sex of nontarget) unweighted-means analyses of variance. The results of these analyses are reported below in terms of their implications for the hypotheses.[4]

Both the less-of-a-connection hypothesis and the double standard hypothesis predict that females should underpay themselves relative to males. In addition, however, females should pay themselves less than other people pay females if the lesser connection is manifested in a weaker sense of own equity, whereas both males and females should pay other females less than they pay males if there exists a general, lower standard of fair pay for women. Thus, we expected either a significant Target × Sex of Target interaction (if the less-of-a-connection was expressed in weaker own equity) or a significant sex of target main effect (if the sex difference in pay was a reflection of different standards). The Target × Sex of Target interaction was significant in both analyses, $Fs(1, 66) = 12.50$ and 11.35, $ps < .001$, for actual and

[3] As noted above, an item on the postallocation questionnaire asked subjects to indicate the sex of the other person. Since this variable was part of the design, and it was crucial when subjects allocated pay to the other, the data of nine persons who answered this question incorrectly were excluded from the analysis. In addition, the data from two other subjects were not used: One subject, on his postquestionnaire, indicated that he was told when he had been telephoned and asked to participate that he was to be paid at a rate of $2/hour, which, in fact is what he paid himself. This occurred only once, since he was one of the first subjects that we examined. He was told this in answer to a question, and we took steps to insure that the assistants who were in charge of scheduling answered such questions more appropriately in the future. A second subject gave very bizarre reasons for his allocation (he paid a female $6).

[4] It is important to note, though, that as expected, the sex of the nontarget had little systematic effect on allocations, since no F ratio involving this variable even approached significance. The means of these F ratios were .940 and .739, for actual and fair pay, respectively.

fair pay, respectively. Table 1, which presents the relevant cell means, indicates that the direction of this effect supports the position that the more tenuous connection between work and pay for women is reflected in a weaker sense of own equity.

Inspection of Table 1 and appropriate individual comparisons (Winer, 1971, p. 384) indicate that females tended to pay themselves less than males paid themselves, $t(66) = 1.89$, $p < .03$ (actual pay), and $t(66) = 3.50$, $p < .001$ (fair pay), and less than other people paid females, $t(66) = 3.86$, $p < .001$ (actual pay), and $t(66) = 2.87$, $p < .005$ (fair pay).

Since the weaker own equity interpretation posits that females will pay themselves less than they pay other females, it seemed reasonable, given the results presented above, to perform individual comparisons of these means. These comparisons provided further support for the own equity explanation, since females were found to pay themselves (see Table 1) less than female allocators paid other females: $M = \$5.19$, $t(66) = 2.86$, $p < .005$, for actual pay; and $M = \$3.77$, $t(66) = 2.36$, $p < .02$, for fair pay. Thus, our evidence indicates that females pay themselves less than males, and this sex difference appears due to a weaker sense of own equity in women.

Table 1
Mean Payment Allocated to Females and Males

Sex of target	Target of allocation: Self[a] Amount (in $)	*n*	Other[b] Amount (in $)	*n*
Actual pay allocation				
Female	3.45	22	5.11	17
Male	4.26	17	3.42	18
"Fair" pay allocation				
Female	2.49	22	3.62	17
Male	3.88	17	3.16	18

[a] Values presented in this column are the average amounts that the subjects of each sex allocated to themselves.
[b] Values presented in this column are the average amounts that subjects (both males and females) allocated to other females and males.

In addition, the simple effects analysis of the Target × Sex of Target interaction indicated that allocators tended to pay other males less than they did other females, $F(1, 66) = 9.62$, $p < .005$ (actual pay); $F(1, 66) = 2.98$, $p < .10$ (fair pay).

Although (as noted above) data collected on a separate sample of students indicated that males and females evaluate their own performance on the task similarly, it still could be that in general, writing essays—a task that requires some reasonable degree of verbal fluency to perform well—is perceived as a task more suited for the "typical" female. To explore this possibility, 307 subjects —students in introductory psychology and social psychology classes—completed a "Campus Issues Questionnaire" and evaluated on a 5-point scale either their own performance or the expected performance of other females or males. These data indicated that there was no difference in the evaluation of performance, either one's own or that of others, as a function of the sex of respondent, $F(1, 301) = .15$. However, there was a difference in evaluation of others' expected performance as a function of their sex, $F(1, 301) = 8.24$, $p < .01$; females were expected to do a better job than males. Thus, it appears that the differential pay given to other females and males was due, at least in part, to the differential expectations that allocators might have had about performance as a function of sex.

In addition, both males and females evaluated their own performance more favorably than they did the expected performance of other persons of either sex, $F(1, 301) = 105.44$, $p < .0001$. Of particular interest is the finding that females evaluated their own performance more favorably than they did the expected performance of either other women, $F(1, 301) = 23.92$, $p < .0001$, or other men, $F(1, 301) = 78.64$, $p < .0001$. Table 2 presents the cell means that are relevant to these effects.

Table 2
Evaluation of Performance on Campus Issues Questionnaire

Sex of target of evaluation	Target of evaluation: Respondent Score	Respondent *n*	Other Score	Other *n*
Female	4.52	118	3.96	44
Male	4.66	105	3.48	40

Note. Scores on this measure could range from 1.0 (i.e., poor performance) to 5.0 (i.e., excellent performance).

Discussion

The results of this study indicate that persons who were recruited for pay, who actually worked for a period of time, and who received payment for their work differed in the amount of money that they paid themselves (and considered to be fair) as a function of their sex. These findings lend support to Mednick and Tangri's (1972) and Chesler and Goodman's (1976) contention that females expect less monetary reward than males for the work that they do.

Results also indicated that this more tenuous connection between work and pay is expressed primarily through a weaker sense of own equity in females. Females paid themselves less than other people paid females, although females also evaluated their own performance more favorably than they did the performance of other females. Thus, it appears that females' payment to themselves was not based entirely on the evaluation of their own performance. On the other hand, both females and males paid other females more than they paid other males, and they evaluated the expected performance of other females more favorably than they did that of males. Since this correspondence between evaluation and pay did not occur when females allocated money to themselves, it appears that women were less apt to apply a standard of fair pay to their own behavior than they were to the behavior of others.

It should be noted, however, that these findings do not necessarily invalidate completely other alternative explanations. Some explanations—for example, that females are more influenced by a norm of equality than are males (Leventhal, 1976; Sampson, 1975) —are not antithetical to the less-of-a-connection hypothesis. In fact, the weaker sense of own equity in females could be a necessary condition that permits these other variables to operate. For example, females might subscribe to the norm of equality because their weaker sense of own equity alone does not provide them with an adequate basis for making a decision about an appropriate distribution of rewards.

The data do, however, tend to diminish the plausibility of a number of alternative explanations. For example, one possible alternative explanation is that the female subjects in this study had been victims of wage discrimination in their pasts, which may have lowered their expectations with regard to monetary payment for work performed. A second alternative suggests that females are less experienced than males (and therefore less "skilled") at the task of determining monetary outcomes. Thus, females may have tended to underreward themselves because of a relative lack of experience in dealing with such matters. Neither of these explanations, however, can account for the amount of money women allocated to female targets. That is, any lowered expectations regarding pay for work as a result of past experience (or inexperience) would most likely generalize to paying other females as well and, therefore, should have resulted in female allocators treating other females in the same way that they treated themselves. Results indicated, however, that this was not the case.

Another potential alternative explanation that is rendered more implausible by the results of the present research is that females are more "moral" or socially responsible than males. The data that are summarized in Table 1 suggest that *both* males and females tended to actually take more for themselves than they indicated they felt was appropriate. Thus, while females paid themselves less than did males, they (as did males) still "took advantage" of the situation and paid themselves more than the amount they reported was appropriate immediately after that allocation.

Thus, there is no indication that females acted in a more moral manner than did males.

As noted above, the greater payment made by allocators to other females, compared to that made to other males, was congruent with differential evaluations of performance as a function of sex. However, examination of the relevant means (Tables 1 and 2) suggests that the amount actually paid to other females was excessive, even given an expected difference in performance. Moreover, the difference between what subjects actually paid other females and males was greater than the difference between what they said was fair pay for the two sexes. Thus, a case can be made that allocators in the present study were being "kind" to females. This conclusion is congruent with the findings of Gruder and Cook (1971) that persons are more helpful to females than to males and those of Messé and Callahan-Levy (Note 3) that allocators tend to be kinder to females when distributing a reward between themselves and another person. The notion of being kinder to females is congruent with the passive, dependent aspects of the traditional female sex role. Thus, if females are persons towards whom others are nurturant and protective, there is no need for them to be concerned with acquiring a reasonable amount of money for their work.

The original impetus for the present research came from an attempt to explain, at least in part, the sex differences that were rather consistently found in studies of reward allocation in which subjects were asked to anonymously divide money between themselves and another person. The present findings suggest that one reason why females appear more generous in such situations is their indifference, relative to males, to receiving "appropriate" money for their work. Study 2, presented below, attempted to replicate this result across a different task and a number of age groups and to relate pay allocation to some consequences of sex role socialization.

Study 2

Given the results of Study 1, it seemed reasonable to explore two related questions: (a) whether sex differences in self-pay allocation occur across a number of ages and (b) whether these differences, if they exist, are related to sex role socialization. To this end, in Study 2, we examined self-pay allocation in first-, fourth-, seventh-, and 10th-grade females and males and measured these subjects' preferences for masculine and feminine occupations and activities.

Studies that have examined reward distribution in children have yielded mixed results. For example, Leventhal and Anderson (1970) found that kindergarten-age females allocated less reward to themselves than did males. On the other hand, Lane and Coon (1972), in a replication of the Leventhal and Anderson study, found no sex difference, and Lerner (1974), in a study that used a similar methodology, found that 5-year-old females allocated more to themselves than did 5-year-old males. The reasons for these discrepant findings are not clear. Although the methodologies employed have much in common, they also differed in many potentially relevant ways—for example, the type of reward that the subjects were asked to distribute—and these differences in procedure could have caused the differences in results.

Given the age of the children who were examined in these studies, it could be that these differences in research findings were due, at least in part, to the complex interpersonal nature of the reward distribution task. It is possible that a more straightforward task—for example, self-pay allocation—would yield more consistent, interpretable findings.

Hartley (1960) found that both males and females, who were as young as 5 years old, were capable of making clear distinctions between men's and women's work roles. Her subjects saw women's work to be centered on homemaking duties (which receive no direct monetary pay), whereas men's work was perceived as a number of tasks for which money was paid. Assuming (a) that the weaker sense of own equity in females is connected to sex role socialization regarding appropriate occupations for men and women and (b) that the consequences of the socialization appear at least by the age of 5 years, it follows that a sex difference in self-pay allocation

Table 3
Mean Ages (and Frequencies) of Female and Male Subjects at the Four Grade Levels

	Grade							
	First		Fourth		Seventh		10th	
Sex	Age (years)	*n*	Age (years)	*n*	Age (years)	*n*	Age (years)	*n*
Female	6.28	7	9.33	12	12.57	11	15.40	10
Male	6.14	14	9.33	9	12.45	7	15.60	10

would occur quite early in children's psychological development. However, as children become more experienced with sex role-related activities, it also seems likely that this difference would be increased. Thus, we expected that the sex difference in self-pay allocation would be greater among adolescent subjects than it would be among younger children.

A fundamental premise of the less-of-a-connection hypothesis is that it is related to sex role socialization, especially those areas of sex role that involve occupational choice. In Study 2, we attempted to examine the premise more directly by measuring preferences for sex-typed occupations and activities and exploring in females the relationship between these measures and their self-pay allocation behavior. We expected that girls who expressed a preference for masculine occupations and activities would be more likely to pay themselves as males do, whereas girls who selected more feminine pursuits would be more likely to underpay themselves relative to males.

Method

Subjects

The subjects were male and female students in the first, fourth, seventh, and 10th grades of schools in a district that serves a lower-middle-class to middle-class suburb of Lansing, Michigan. Table 3 presents the frequencies and mean ages of the subjects. In each class the teacher introduced the experimenter to his or her students. The experimenter explained to the class that the students were needed to perform a job—participating in an interview that involved "things that you might like to do." Parental permission was obtained for all those students who agreed to participate. Of all the students who were contacted, only one, a female 10th-grade student, declined to take part.

Table 4
Presentation Order and Femininity Ranking of Items in the Activities and Occupations Scales

	Scale			
	Activities		Occupations	
Order of presentation	Item	Ranking	Item	Ranking
1	Playing football	10	Firefighter	9
2	Sewing or knitting	1	Secretary	1
3	Shoveling snow	9	Football player	10
4	Cooking or baking	2	Nurse	2
5	Going camping	8	Astronaut	8
6	Dancing	3	Teacher	3
7	Going bowling	7	Police officer	7
8	Swimming	6	Parent	4
9	Ice skating	4	Doctor	6
10	Reading	5	Baker	5

Interview Schedule

The instruments used in the study were administered to subjects via an interview protocol, which was the "task" for which subjects were paid. This interview required approximately 25 minutes to complete. A female or male undergraduate experimenter (counterbalanced with respect to sex of subject) administered the interview individually.

The interview began with a number of questions about personal and family demographic characteristics, for example, age of subject, family size, and parents' employment status. Then, subjects were presented with a list of 10 activities. This list was obtained through research that established, via a modified Thurstone procedure, that these activities differed significantly with respect to the degree of femininity and masculinity associated with them. Table 4 presents these activities ranked as a function of their perceived femininity, and it also indicates the order in which the activities were given to the subjects. The experimenter read through the list twice and then asked each subject to indicate her or his three most preferred activities.

Next, subjects were presented with 10 occupations. These occupations were selected to vary along the feminine–masculine dimension and were obtained via the same procedure that we used to construct the Activities scale. The 10 occupations, their rank order in terms of femininity, and their presentation order also are given in Table 4. The Occupations scale was administered to subjects in exactly the same manner as was the Activities scale.

Following the presentation of the Occupations scale, the experimenter administered a short form (10 items) of the Bialer-Cromwell Locus of Control Scale for Children (Bialer, 1961). This scale consists of statements that require a yes–no answer.

Next, subjects were given instructions concerning their self-pay allocation (see below), which they performed. Then, the experimenter asked three questions about each subject's evaluation of his or her performance. The exact wording of these questions is presented in Table 5. Finally, the experimenter asked the subject what she or he thought was the "fair amount" of pay for doing this work.[5]

Pay

Prior to Study 2, via extensive pilot testing, we obtained a measure of what children considered to be appropriate pay for participation in an experiment of this type. This evaluation was necessary so that subjects could be presented with an amount of money with which to pay themselves that was in great excess of a consensus standard of what was fair. This pilot research revealed that children considered appropriate pay to be less than $1, and thus, $3 in dimes was the amount of money presented to each subject.

Table 5
Mean Responses of Female and Male Subjects to Questions About Their Own Performance

Interview question	Females (n = 40)	Males (n = 40)
1. How well do you feel you did at this "job"?	2.52	2.70
2. Do you think you did better than most boys your age would do?	2.15	2.18
3. Do you think you did better than most girls your age would do?	2.10	2.30

Note. Subjects answered all questions using a 3-point scale. Thus, scores could range from 1–3, with higher scores indicating a higher evaluation.

Also, there was some question about the appropriateness of money as a reward for 6-year-old first graders. Pilot testing indicated that most first graders were confused about the value of coins, but that they were interested in, and understood, the value of Hershey "kisses." This pretesting also indicated that children in first grade saw less than 10 "kisses" as fair pay for being interviewed. Thus, we presented subjects in this grade level with 30 Hershey "kisses," so that they could take what they wanted as their pay.

Variables and Experimental Design

The design of Study 2 was both experimental and correlational. Sex of subject and grade level were examined through a 2 (female, male) × 4 (first, fourth, seventh, and 10th grades) factorial design with two dependent measures: (a) the amount of reward that subjects actually allocated to themselves and (b) the amount of reward that subjects indicated was fair pay. In addition, the two pay measures were correlated with the two measures of sex role preference, scores on the locus of control measure, and the 12 biographic–demographic questions (e.g., age of subject, number of brothers, employment status of the father, etc.).

[5] The interview was worded exactly the same for all subjects. Thus, care was taken to insure, via pilot testing, that the younger children could understand the meaning of the questions.

Procedure

A major goal in designing the present research was to replicate as closely as possible the essential features of the design and procedure used in Study 1.[6] Study 2 was conducted in large classrooms at the schools that the subjects normally attended. Approximately 10 subjects, both male and female, were interviewed at the same time, but each was interviewed by a different experimenter, and they were always well separated within the room. Subjects were seated so that they faced the experimenter, who had her or his back to the wall, and so that no subject could see or communicate with other subjects in the room.

At first, subjects were given general instructions that informed them that they were about to complete a "job" for a class of students at Michigan State University. They were asked to take this job as seriously as possible and to do their best to answer the interview questions honestly and accurately, although there would be no right or wrong answers to whatever they were asked. They also were reminded that as promised earlier, they were to be paid for their time after they completed the job. Then the experimenter administered the interview schedule to the subject, a procedure that took approximately 25 minutes to complete.

At the completion of the interview, the subject was given the opportunity to pay herself or himself. The subject was told that her or his job was completed and that it was time to be paid. The rationale that was given for this self-payment procedure was as follows:

> We have some money to pay you. The only problem is, we don't know what fair pay is for a job like this for someone like you. So we've decided to let each person take what they feel is a fair amount of money for their work. This means we want you to take what you feel you deserve.

The experimenter also stressed that there was no "correct" amount and that the subject would actually keep the amount that she or he chose.

After the subject received these instructions, the experimenter placed 30 dimes (or candies, for first-grade subjects) on a large cardboard and gave the subject a blank envelope and an envelope marked "Leftover." Subjects were instructed to put what they wanted in the blank envelope, which they would keep, and to put the remainder in the envelope marked "Leftover." The experimenter stressed that she or he would turn around and not look or, if possible, leave the room, so that no one would know how much money (or candy) the subject actually kept. The subject also was told that any leftover money (or candy) would be returned to Michigan State University to be used for other studies.

Results

As in Study 1, there were two measures of allocation behavior: (a) the amount of money that subjects actually allocated to themselves as pay and (b) the amount that subjects indicated they felt was fair pay on a postallocation question. Summary data for the self-allocation dependent measures are presented in Table 6, which presents the mean number of payment units (candy in the first grade, dimes in the fourth, seventh, and 10th grades) actually kept and indicated as fair pay by males and females at the four grade levels.

The amount of reward subjects actually kept and the amount they indicated was fair pay on the relevant postallocation question were subjected to 2 (sex of subject) × 4 (grade level) unweighted-means analyses of variance (ANOVAs). As in Study 1, the two ANOVAs produced essentially the same results. The ANOVAs revealed two significant effects: the main effect for sex of subject, $F(1, 72) = 15.54$, $p < .001$ (actual pay), and $F(1, 72) = 9.22$, $p < .005$ (fair pay), and the main effect for grade level, $F(3, 72) = 13.39$ (actual pay) and $F(3, 72) = 8.37$ (fair pay), both ps $< .001$. As expected, Table 6 shows that the main effect for the sex of subject reflected a tendency in males to allocate greater pay to themselves than did females and to perceive that more pay was fair. Table 6 also shows that as the grade level increased, the amount of reward that they felt was fair pay tended to decrease. Comparisons performed on the two scores between adjacent grade levels across both sexes indicated that there was a very significant decrease in the amounts kept and thought to be fair between the fourth and seventh grades, $F(1, 72) = 27.64$

[6] Study 1, however, recruited college-age subjects for pay through an advertisement in the campus newspaper. Although the subjects in Study 2 were essentially volunteers who were also recruited for pay, the act of volunteering required very little effort on their part. In fact, many of the elementary, junior high, and senior high students appeared to welcome the opportunity to be excused from class for the time required by the study. Thus, one essential difference between the two studies is the motivation of subjects for the pay offered. It is not possible to determine the degree to which this difference might have affected the interpretation of the results, but it is assumed that these differences in motivation would be uniform across sex, within grades.

Table 6
Mean Payment (in Units of Pay) That Females and Males Allocated to Themselves at Each Grade Level

Sex of subject	Grade level: First Amount	n	Fourth Amount	n	Seventh Amount	n	10th Amount	n
			Actual pay allocation					
Female	10.86	7	12.92	12	3.73	11	2.40	10
Male	16.57	14	18.56	9	6.57	7	10.70	10
			"Fair" pay allocation					
Female	10.14	7	9.17	12	4.64	11	3.00	10
Male	14.86	14	15.44	9	5.29	7	8.50	10

actual pay) and 12.43 (fair pay), both ps < 001.

Analysis of variance tests the significance f interval rather than ratio differences, and ıese interval differences tend to be con- trained by the total score over the cells of a iven comparison. Both male and female sub- ects in the higher grades took much less than id their younger counterparts; in fact, by ıe seventh grade, the mean self-allocation as only about five units, across sex. This latively small amount of pay had the effect f constraining the size of the interval differ- nces between the conditions of sex within ıe older grades and, thus, would tend to inimize the magnitude of the obtained Sex Grade Level interaction ($F < 1.00$, in both nalyses). Therefore, in an attempt to ex- mine the possibility that sex, in fact, did in- uence allocation of pay differentially across ade levels, actual and "fair" female scores ere transformed to proportion scores, which represented the females' proportion of the mean males' score at each grade level. For example, each first grade female's actual and fair scores were divided by the respective actual and fair means of the first grade males' scores. In this way, an analysis could be performed on ratio scores, rather than on the more constrained interval units.

These female proportion scores were subjected to one-way (grade level) analyses of variance. These analyses revealed that the effect of grade level was significant for actual pay, $F(3, 36) = 4.94$, $p < .01$, but not for fair pay, $F(3, 36) = 1.20$, $p > .1$. The means of these proportion pay scores over the four grade levels are presented in Table 7. Planned comparisons (Winer, 1971, p. 384) performed between adjacent grade levels revealed that as predicted, the actual pay proportion scores for the 10th-grade females were significantly less than the scores for seventh-grade girls, $t(34) = 2.55$, $p < .02$. This also was the case

able 7
lean Proportion of Average Male Pay That Females aid Themselves in Each Grade

Pay score	Grade level: First (n = 7)	Fourth (n = 12)	Seventh (n = 11)	10th (n = 10)
Actual	.66	.69	.57	.22
Fair	.68	.59	.88	.35

for fair pay proportion scores, $t(34) = 1.88$, $p < .05$, even though the overall effect of grade level was not significant.

The possibility that the sex difference in self-pay was due to differences in the males' and females' evaluations of their own performances was examined through 2 (sex of subject) × 4 (grade level) analyses of variance, performed on the three questions that were relevant to this issue that were asked during the postallocation portion of the interview.

Table 5, which presents the mean responses to these questions as a function of sex of subject, indicates that there was little difference between males and females in their self-evaluations. The results of the three analyses of variance supported this conclusion, since no effect attributable to sex of subject was statistically significant, (Fs = .08 to 2.60). Thus—as was the case for the findings for Study 1—the sex difference in self-pay allocation does not appear to be due to any underlying difference in performance evaluation.

We expected that scores on the sex role preference scales would correlate with self-allocation behavior. It should be noted that t tests comparing the median rank of the three items that were selected by a male or female subject for both the Activities scale (female $M = 5.85$, male $M = 8.50$) and the Occupations scale (female $M = 3.98$, male $M = 8.43$) were highly significant, ts(78) = 8.35 and 16.70, respectively, ps < .001. The two scales also were significantly correlated with each other, $r(76) = .65$, $p < .001$. As mentioned previously, we expected that scores on the sex role preference scales would correlate with self-allocation behavior in females, such that more masculine preferences would relate to more masculine payment behavior. To test this prediction directly, the proportion of the average male payment in her grade level that each female took for herself was correlated with the median rankings of her selected occupations and activities. The resultant correlation coefficient revealed that scores on the Occupations scale correlated substantially with proportion scores, $r(38) = .66$, $p < .001$, indicating that as expected, the more masculine the occupational orientation, the more masculine the allocation behavior. The correlation coefficient computed for scores on the Activities scale and the proportion payment scores was in the predicted direction, but was not statistically significant, $r(38) = .15$.[7]

The payment scores also were correlated with the locus of control measure and the demographic variables. None of these correlations, however, yielded statistically significant findings.

Discussion

The findings of Study 2 replicate closely those of Study 1. Females—even the females in the first-grade sample—tended to pay themselves less than did males at the equivalent grade level, as did the college student females who were the subjects in the first study. Moreover, the sex differences in self-pay that were found in both studies do not appear to be a function of differential evaluations of task performance. Thus, findings of the two studies taken together provide strong, albeit indirect, support for the proposition that females are socialized to have a weaker sense of their own equity.

There were some slight differences between the findings of the two studies, however. For example, the 10th-grade sample of Study 2 was closest in age to the subjects in Study 1 and yet the sex difference at this grade level was substantially larger than was evidenced in the college student sample. It is likely that this difference in results is attributable to differences between the two studies in terms of such factors as (a) the manner in which subjects were recruited to participate—which probably caused systematic differences in subjects' motivation for money—and (b) the tasks that were used as the basis for allowing

[7] It is of interest to note that the comparable correlations for males (i.e., relating femininity–masculinity of occupational and activity choices to self-pay) were similar to those for females, but of lower magnitude. Specifically, the correlation between occupational preference and self-pay was .24, $p < .075$, while, again, it was considerably lower for activity preference and self-pay ($r = .04$).

subjects to pay themselves. It is possible that these and other factors mediate the magnitude of the sex difference. However, it is noteworthy that the sex difference in self-pay allocation did appear under such different conditions and in somewhat different subject populations.

Given Hartley's (1960) findings that young children to some extent have internalized the traditional division of labor as a function of sex, we expected some degree of sex difference in self-pay behavior in our first-grade sample. However, it seemed reasonable that this sex difference would be greatest when the allocators were closest to the age at which they were expected to assume the adult sex role. Thus, we also expected that the relative difference between male and female self-pay would be greatest for our 10th-grade sample.

Findings supported both these expectations to some extent. In fact, though, the difference in the first-grade sample was somewhat stronger than we had originally expected. The magnitude of this finding suggests that the consequences of that portion of sex role socialization that involves economic activities become evident at a rather early age. The proportional difference in self-allocation as a function of sex was greatest, as expected, in the 10th grade, but, as noted above, this increase was not evident when interval differences were examined. This disparity, as we suggested, could be due to the constraints placed on the seventh- and 10th-grade data due to the relatively small amount of money that both males and females in these grades paid themselves. On the other hand, there is the possibility that the hypothesized increase is not really that strong. Thus, it seems reasonable that future research should examine this issue—and that of the comparability of 10th graders and college students—by asking samples of seventh-grade, 10th-grade, and college student male and female subjects to pay themselves after they work on a more challenging task, one that would provide them with a sound basis for taking a reasonably large amount of money.

We hypothesized that females and males differ in their allocation behavior as a consequence of differences in sex role socialization, and thus, this behavior in females should be related to other manifestations of their sex role. Findings of Study 2 indicated that this was the case, since self-pay allocation in females correlated strongly with the femininity–masculinity of occupation preferences. It is interesting that a less specifically economic index of femininity–masculinity (i.e., activities) did not yield a significant relationship with self-pay allocation. If this specific finding is a valid reflection of this relationship in general, it would suggest that the sense of one's own equity is a consequence of a somewhat narrow range of socialization experiences: those that involve rather specifically the economic area of human endeavors.

Conclusions

The findings of the two studies also appear to have more general implications. The well-documented lack of parity in pay that exists between female and male members of the work force in American society to some extent could be the result of a willingness on the part of women to work for lower wages than men. Mednick and Tangri (1972) and Chesler and Goodman (1976) contend that one factor that has contributed to this willingness is the different degree to which work and money are related in females and males. The present research does provide evidence in support of this assertion.

In addition, the results of the present work, as well as the preponderance of past studies, strongly suggest that women tend not to act in ways that maximally benefit them economically. It could be argued that the "feminine" orientation toward money, in fact, is more psychologically healthy. However, it is nevertheless the case that such an orientation literally is costly to those persons who hold it, especially since it makes them vulnerable to exploitation by persons who have more self-serving ideas about money and work.

These conclusions have important implications for the evaluative examination of traditional sex roles that currently is being undertaken within and outside of psychology. For this reason alone, they merit and require further examination.

Self-Esteem, Self-Consciousness, and Task Performance: Replications, Extensions, and Possible Explanations

Joel Brockner
State University of New York College at Brockport

Previous research has suggested that the task performance of low-self-esteem individuals (low SEs) is impaired under conditions designed to increase self-focused attention. Task-focusing, rather than self-focusing, manipulations have actually bolstered the achievement of low SEs. The present studies were designed to replicate and extend these findings. The results of two experiments demonstrated that the performance of low SEs (but not of individuals with higher self-esteem) was affected by a variety of attentional manipulations. As before, task-focusing instructions enhanced and self-focusing stimuli impaired their performance on a concept formation task. Similar results were obtained for individuals who scored high (but not for those who scored low) on an individual difference measure of self-consciousness. Study 2 also demonstrated that when the task-focusing manipulation worked, it neutralized the adverse effects of the self-focusing stimulus on the low SEs' performance. Supplementary data suggested that the manipulations generally had their intended effects on attentional focus and that attentional focus influenced performance. It is hypothesized that the low SEs' level of self-focused attention influenced performance through the mediating effects of anxiety.

Self-esteem (SE) theorists and researchers have established that relative to high-self-esteem people (high SEs), low-self-esteem individuals (low SEs) are more likely to suffer from a variety of emotional and behavioral problems (e.g., greater anxiety, less happiness; Coopersmith, 1967) and more likely to become alcoholics (Wahl, 1956). Perhaps because low SE has so many undesirable correlates, clinical, social, and personality psychologists have long been concerned with uncovering effective methods of enhancing the self-evaluations of low SEs. Unfortunately, this task has proven quite difficult, since low SEs seem to be trapped in a vicious, self-defeating cycle of low SE. For example, many studies (Hamachek, 1971; Shrauger, 1972) have shown that low SEs do more poorly than high SEs in achievement settings (i.e., situations that have evaluative implications for one's SE). Poor performances, in turn, would seem to set the stage for continued self-criticism and low SE. Thus, of potentially critical importance are the precise reasons for the often deflated task performance of low SEs.

Low Self-Esteem and Self-Focused Attention

One of several possible causes of low SEs' poor task performance may be their focus of attention while engaging in the task. Specifically, there is converging evidence that low SEs are generally more self-conscious or self-focused than high SEs. Turner, Scheier, Carver, and Ickes (1978) discovered a significant negative correlation between individual difference measures of self-esteem and self-consciousness (Fenigstein, Scheier, & Buss, 1975). In addition, recent findings from

The author would like to thank John Eckenrode, Herb Fink, Larry Hjelle, Jeff Rubin, Larry Wallnau, and two anonymous reviewers for their insightful comments on an earlier version of the manuscript. In addition, he is greatly indebted to Blethyn Hulton and Dyan Wallnau for their competent assistance in collecting the data.

the objective self-awareness literature suggest an inverse relationship between self-focused attention and SE. For instance, Ickes, Wicklund, and Ferris (1973) found that subjects who completed a SE inventory in the presence of a self-focusing stimulus (a mirror) rated themselves significantly lower than those in a no-mirror condition. Also, self-focusing stimuli cause people to behave like low SEs. For example, both Duval (1976) and Wicklund and Duval (1971) found greater conformity when subjects were exposed to self-focusing stimuli. In parallel fashion, low SEs have also exhibited higher levels of conformity in some studies (e.g., Janis, 1954), although the evidence here is not totally consistent. Taken together, however, the evidence seems to implicate an inverse relationship between SE and self-focused attention.

Self-Focused Attention and Task Performance

The task performance of low SEs may be impaired by their heightened self-focused attention for at least two related reasons: (a) Given that attentional capacities are finite, low SEs will not be able to devote sufficient attention to the task, and (b) low SEs may well focus on their own negative characteristics (Mischel, Ebbesen, & Zeiss, 1976), leading to anxiety. Anxiety, in turn, may impair performance, particularly on complex tasks (e.g., Spence, Farber, & McFann, 1956).

This is not to say, however, that low SEs will *always* be more self-conscious than high SEs and/or perform more poorly than high SEs. For example, if the task is inherently engaging, one might expect all subjects' self-focused attention to be reduced. Under such conditions there may be no relationship between SE and performance. In fact, Brockner and Hulton (1978), Shrauger (1972), and Shrauger and Terbovic (1976) found that low and high SEs performed equally well on a concept formation task that naturally captured the subjects' attention. Nevertheless, when self-focusing stimuli were introduced into the experimental situation (i.e., an audience in the Shrauger, 1972, study and an audience and mirror in the Brockner and Hulton, 1978, experiment), the performance of the low SEs dropped markedly, whereas the high SEs maintained their high level of performance. Hence, even if low SEs are not already more self-conscious than high SEs, it would seem that their susceptibility to becoming self-focused is considerably greater than high SEs'.

If the task performance of low SEs is impaired by heightened self-focused attention and/or a greater propensity to become self-aware, then any manipulation that enhances task-focused and decreases self-focused attention should improve their performance. Indeed, Brockner and Hulton (1978) discovered that low SEs actually performed better than high SEs when both groups were given a set of instructions designed to increase task focusing. These data may be of considerable practical significance, in that the favorable performance of the low SEs may serve as a starting point for breaking the vicious cycle of low SE. That is, it is entirely possible that with repeated success experiences in achievement settings, low SEs will elevate their self-evaluations to a more positive level.

Questions Addressed by the Present Research

The tendencies for low SEs in the Brockner and Hulton (1978) study to perform poorly in the presence of self-focusing stimuli and favorably when instructed to focus on the task raised a number of theoretical and practical questions. First, could the various findings be replicated? Do self-focusing stimuli consistently impair the low SEs' task performance? This is an important question from a practical or applied vantage point. If self-focusing stimuli consistently impair low SEs, this may help us identify (and perhaps start to change) the factors that might ultimately perpetuate low SE. From a more theoretical viewpoint, experimental social psychologists have witnessed a great resurgence of interest in the notion of self-consciousness. To study the effects of self-consciousness, many investigators have manipulated self-focused attention with mirrors, video cameras, and audiences and tested its effect on a variety of behaviors (see Duval & Wicklund, 1972). The present formulation views self-esteem as a factor related to a person's self-

focusing tendencies. Thus, it would be useful to know how this individual difference variable interacts with situational manipulations of self-consciousness.

Second, could the task instructions results be replicated? Given that the instructions enhanced the low SEs' performance and that enhanced performance might begin to break the vicious cycle of low SE, it would be important to know if these instructions reliably improve the low SEs' performance.

Third, can the results be extended? An important condition missing from the Brockner and Hulton (1978) study is one in which the self-focusing stimuli and task-focusing instructions are combined. What happens when these two manipulations with opposite effects on performance and presumably opposite effects on attention are pitted against each other? Do the two stimuli tend to cancel each other, does one override the other, or do they produce some other kind of interaction effect?

Fourth, if the results can be replicated and extended, what are the appropriate explanations for the data? To what extent are attentional processes influencing performance? Brockner and Hulton (1978) used several manipulation checks of attentional focus, and while the results on these items were generally consistent with performance, the manipulation check data were somewhat weak. The present research included additional manipulation checks that may give a more valid indication of subjects' focus of attention. Two studies were conducted to answer the above questions.

Study 1

Subjects were given a pretest measure of their self-esteem and completed the identical concept formation task used by Brockner and Hulton (1978). One third of the subjects completed the task in the presence of self-focusing stimuli. The stimuli used in this study were a video camera and a mirror. Hence, this condition will be referred to as the video–mirror condition. Note that a different procedure was used by Brockner and Hulton, who had subjects work on the task before an audience that was observing them from behind a one-way mirror. To strengthen a possible attentional interpretation of the results, a different operationalization of self-focused attention was employed in the present experiment. One third of the subjects were provided with the identical task-focusing instructions used by Brockner and Hulton (the task condition). The other third of the subjects received both the self-focusing *and* task-focusing manipulations (the combined condition). In sum, a two-factor (SE × Attentional Treatment) between-subjects experiment was conducted. It was expected that the manipulations of attentional focus would have the most pronounced effects on the low SEs' task performance. Following the results of Brockner and Hulton (1978), it was predicted that compared to high SEs, low SEs would perform significantly worse in the video–mirror condition and significantly better in the task condition. Given the seemingly greater salience of the self-focusing versus the task-focusing manipulation, it was expected that the low SEs would perform somewhat worse than high SEs in the combined condition.

Method

Participants

The 88 volunteer subjects (53 male, 35 female) were summer school students at a Vermont state university. Each subject received $3 for participating.

Materials

Self-esteem inventory. The inventory was identical to the one used by Brockner and Hulton (1978) and Shrauger (1972). The scale measured the subjects' perceived competence across 16 various situations (e.g., academic, athletic, social). Subjects had to indicate the percentage of time a particular behavior or outcome applied to them (e.g., "When meeting new people for the first time, what percentage of the time are you able to impress them favorably and form good relations?"). Nine items were worded so that higher percentages indicated higher SE, whereas seven were phrased so that lower percentages indicated higher SE. For the latter items, the subjects' percentage ratings were subtracted from 100. The average score for all 16 items was computed such that higher scores represented higher SE. The mean score for all subjects was 70.36 ($SD = 9.40$). Subjects were classified as high or low SEs on the basis of a median split (high SEs: $M = 77.27$, $SD = 5.91$; low SEs: $M = 63.14$, $SD = 6.49$). Subjects

were randomly assigned to predetermined attention conditions. As a result there was an unequal distribution of subjects across conditions. Nevertheless, *within* each SE level the mean SE scores across conditions were virtually identical.

Concept formation task. The task was identical to the one employed by Brockner and Hulton (1978). Specifically, 32 squares were attached to a 14 × 25 × .25 inch (36 × 64 × .6 cm) wooden board. Each square had five characteristics: number (one or two), size (large or small), color (black or white), shape (circle or square), and position (left or right). Beneath each square a small hole had been drilled in the wooden board.

The subject was told that the concept would consist of one, two, or three characteristics. The experimenter selected a square that was an example of the correct concept. The subject's task was to determine the concept by lifting up other squares, one at a time. If the square was an example of the correct concept, the word *yes* was written on a piece of oak tag that had been inserted below the board. If the square was not an example of the correct concept, the word *no* had been written below. When subjects believed that they had ascertained the correct concept, they wrote it on a slip of paper provided to them. At no time were subjects ever informed of the accuracy of their responses. Subjects were told that while "we are interested in the speed and accuracy with which you determine the concepts, it is more important to be accurate." There were seven trials, which all participants completed in an identical random order. After subjects completed each trial, the experimenter removed the underlying piece of oak tag for that trial and inserted the piece containing the feedback for the next trial.

Procedure

All participants were run one at a time. Upon entering the laboratory they were led to a cubicle and were told that the experiment would consist of a number of parts. In the first part they were asked to complete the self-esteem inventory. After completing this measure they were led to another cubicle where they found the concept formation task and the accompanying instructions. Subjects were asked to read the instructions to themselves while the experimenter simultaneously read them aloud. The instructions informed subjects how to determine the concepts. In addition, subjects were provided a practice trial to familiarize them further with the task. During the practice trial the experimenter directed the subject toward the correct concept whenever necessary. However, subjects always had to determine the concept themselves on the practice trial.

After the practice trial was completed, the focus-of-attention manipulations were introduced. In the video–mirror condition, the experimenter placed a large mirror (24 × 36 inches—61 × 91 cm), which had been hitherto unexposed, directly in front of the subject. Because the mirror was so large, subjects could see not only themselves but also the experimenter observing them as they worked on the task. Also, the experimenter uncovered a video camera and pointed it directly at the subjects, saying:

> Since we are interested in how people go about forming concepts, a video camera has been placed to your right. We will be making a videotape of you and your concept formation strategies. This tape will aid us greatly, as we will be able to observe you an unlimited number of times in the future when we play back the tape. Furthermore, you will notice the mirror in front of you. This will help the experimenter observe you as you are working on the task.

The experimenter then switched on the video-recording unit. In the task condition the experimenter told the subjects:

> OK, now that you are familiar with the task, let me just give you the following advice. This task is not *extremely* difficult, although it *can* be somewhat tricky. Therefore, I can't emphasize strongly enough just how important it is that you maintain your complete and undivided attention on the task at all times. People who have done this experiment in the past frequently mentioned the importance of concentrating on the task at hand. So just remember to keep focusing on the task as much as possible. Again, I can't emphasize this strongly enough.

In the combined condition subjects received both of the manipulations used in the conditions mentioned above. The order in which the self-focusing versus task-focusing stimuli were introduced was counterbalanced. Since the order variable produced no effects on performance, it will not be considered further.

After the focus-of-attention manipulations had been introduced, subjects began to work on the task. The experimenter was seated adjacent to the subject, recording the amount of time that she or he took and the number of squares looked at for each trial. While the experimenter was clearly aware of the subjects' focus-of-attention conditions, he was not aware of their self-esteem scores. When the seventh trial was completed, the experimenter asked subjects to complete a postexperimental questionnaire measuring their attentional focus and felt anxiety while working on the task. In addition, subjects were asked to write their perceptions of the purposes of the study. None of the subjects was able to guess the true nature of the study, and their few suspicions were unrelated to the actual concerns of the experiment. Finally, participants were carefully debriefed, thanked for their participation, and requested not to speak to future subjects about the study.

Table 1
Task Performance, Study 1

Measure	Self-esteem: High *n*	High *M*	High *SD*	Low *n*	Low *M*	Low *SD*
Performance in each condition						
Focus of attention						
Video–mirror	14	1.86	1.59	16	2.81	2.55
Combined	17	2.23	2.31	12	3.92	2.10
Task	14	3.14	2.45	15	3.20	2.79
Internal analysis						
Task concentration						
High	23	2.35	2.03	20	2.05	1.75
Low	22	2.45	2.41	23	4.30	2.69

Note. Performance was measured by errors. Scores ranged from 0 to 9. Thus, the higher the score, the poorer the performance.

Results and Discussion

Performance [1]

Both errors of commission and errors of omission were summed over the seven trials to determine task performance. Thus, if the subject had written a characteristic that was not part of the concept, it was scored as an error. If the subject had omitted a characteristic that was part of the concept, an error was assessed. For example, if the subject had written "one" when the concept was "left square," three errors were assessed.

A preliminary t test yielded no effect as a function of sex of subject. Thus, all data were analyzed with a two-factor unweighted-means analysis of variance. The only effect to approach significance was the self-esteem main effect, $F(1, 82) = 2.98$, $p < .10$, with low SEs making more errors. However, from Table 1 it can be seen that this effect was only obtained in the video–mirror and combined conditions (i.e., when the self-focusing stimuli were present). Several preplanned t tests revealed that low SEs made more errors than high SEs in the presence of the mirror and camera, $t(57) = 2.08$, $p < .025$, one-tailed,[2] with no difference between groups in the absence of these stimuli (i.e., in the task condition; $t < 1$).

Focus-of-Attention Manipulation Checks

Contrary to the results of Brockner and Hulton (1978), the task-focusing instructions had no ameliorating effect on the low SEs' performance in the task condition. However, the focus-of-attention measures will also show that the task-focus instructions did not have their predicted effects (i.e., the manipulation did not work). To test for their attentional focus during task performance, subjects completed the following items on the postexperimental questionnaire (all questions were completed using 41-point scales, with higher scores representing greater endorsement of the statement): *"While you were completing the task,* (a) how self-conscious did you feel, and (b) how hard were you concentrating on the task?" On the self-consciousness item,

[1] For both studies only the error data will be reported. The amount of time subjects took and the number of squares they looked at for each trial were also recorded. However, individual subject variability was quite high on both measures. As a result there were no significant effects for either measure in the two studies (all Fs < 1).

[2] Winer (1971) states that t tests are permissible for meaningful comparisons planned prior to the inspection of the data. Since an a priori directional hypothesis had been proposed, the one-tailed test was employed.

the only effect to emerge was a focus-of-attention main effect, $F(2, 82) = 4.02$, $p < .025$. All subjects were *more* self-conscious in the task condition than in the other two. Likewise, on the task concentration item, there was no evidence that the task-focusing instructions enhanced the low SEs' task-focused attention. In fact, low SEs were least task focused in the task condition.

In essence, then, the task-focusing instructions were ineffectual in this study, as the performance and attentional focus data suggest. If so, one would expect low SEs to become more self-conscious and perform more poorly than high SEs not only in the video–mirror condtion but also in the combined condition. As already stated, low SEs did perform worse than high SEs in both conditions. Moreover, there is additional evidence that low SEs were more self-conscious in both conditions. In addition to completing the self-consciousness manipulation check, the subjects in the video–mirror and combined conditions only were asked, with the 41-point scale format, "While you were completing the task, (a) how aware of the mirror were you, and (b) how aware of the video camera were you?" Each of these items correlated highly with reported self-consciousness: self-consciousness and mirror awareness, $r(57) = .48$; self-consciousness and video camera awareness, $r(57) = .58$; both $ps < .001$. Therefore, all three items were summed into a self-focused attention index. As predicted, low SEs were significantly more self-focused than high SEs, $t(57) = 1.85$, $p < .035$, one-tailed.

Internal analysis. Although the task-focus instructions did not enhance the low SEs' task concentration, one may still wonder if the low SEs who were concentrating on the task performed better than those who were not. Therefore, subjects were classified, by a median split on their task concentration scores, as high or low in task-focused attention. The summary data for the subsequent two-factor (SE × Task Concentration) analysis of variance are presented in Table 1. Interestingly, an interaction effect was obtained, $F(1, 84) = 4.73$, $p < .05$, demonstrating that low SEs only performed worse than high SEs when subjects were not highly task focused. In fact, when both groups reported high task concentration, there was a nonsignificant tendency for low SEs to perform better than high SEs.

In sum, the present study replicated Brockner and Hulton's (1978) finding that self-focusing stimuli cause low SEs to perform more poorly than high SEs. However, the task-focusing instructions did not work in this study—they did not increase task-focused, relative to self-focused, attention or enhance the performance of low SEs. Therefore, there were several reasons to perform an additional study. First, it was unclear if the task condition results were simply due to a failure of the manipulation. An alternative explanation is that the task-focus instructions also enhanced the low SEs' ego involvement or evaluation apprehension. Quite possibly these processes negated the potentially beneficial effects of the task-focus instruction on the low SEs' performance. For example, Sarason (1972) has convincingly demonstrated that evaluative or ego-involving situations cause severe performance decrements for high test-anxious subjects, a group who greatly resemble low SEs. Thus, it would be useful to know how low SEs would perform if there were independent evidence that the task-focus manipulation was successful. Specifically, if the low SEs' performance also improved, then the task condition results of Study 1 would seem to be due to a failure of the manipulation. However, if their performance did not improve even when there was evidence that the manipulation was successful, then the manipulation failure hypothesis would be less plausible.

Second, in light of the failure of the task condition manipulation, the combined condition results are also somewhat ambiguous. That is, is it the case that the self-focusing stimuli actually overpowered the task-focus instructions? Or, were the task-focus instructions, as in the task condition, not successfully manipulated? It would seem that a more convincing test of the combined effects of self-focusing and task focusing would occur if it were at least shown that each stimulus reliably affected attention when manipulated in isolation.

Study 2

The procedures used were in many ways identical to those employed in Study 1. There were, however, several important differences that should be noted. First, a control condition was included, in which subjects received neither the self-focusing nor the task-focusing manipulations. Three studies (Brockner & Hulton, 1978; Shrauger, 1972; Shrauger & Terbovic, 1976) have shown no SE differences in performance on this task in control conditions. However, the addition of this condition made it possible to combine factorially the task-focusing and self-focusing variables. Thus, this experiment consisted of a three-factor design (SE × Task Focus × Self-Focus).

Second, the specific operationalization of self-focused attention was altered somewhat to provide further converging evidence on the joint effects of SE and self-focused attention on performance. That is, only the mirror, and not the video camera, was used in this study.

Third, in addition to responding to the SE inventory, subjects completed an individual difference measure of self-consciousness—the scale recently developed by Fenigstein et al. (1975)—prior to performing the concept formation task. If the interfering effects of self-focusing stimuli and the enhancing effects of task focusing for low SEs are related to the higher self-consciousness of low SEs, then highly self-conscious subjects (high SCs) should respond like low SEs. Thus, the mirror should impair and the task-focus instructions should bolster mainly the high SCs. Parallel findings for low SEs and high SCs (and for high SEs and subjects low in self-consciousness, low SCs) would provide converging evidence that performance was influenced by attentional processes.

Method

Participants

The 119 participants were drawn from an introductory psychology class at a New York state college. All received extra course credit for their participation. Of the 119 subjects, seven were eliminated for failure to understand the instructions. The proportion of eliminated subjects was not related to any independent variables. The final sample consisted of 112 subjects (50 male, 62 female) who were unequally distributed across the various experimental conditions.

Materials

Self-esteem inventory. The scale was identical to the one used in Study 1. The mean score for all subjects was 68.41 ($SD = 9.57$). Subjects were divided into three groups. The upper third of the distribution were labeled high SEs ($M = 79.05$, $SD = 5.49$); the middle third, medium SEs ($M = 68.21$, $SD = 2.59$); and the bottom third, low SEs ($M = 57.97$, $SD = 4.21$).

Self-consciousness inventory.[3] Subjects were asked to indicate on 6-point scales (minimum = 0, maximum = 5) how much each statement was characteristic of them (e.g., "I reflect about myself a lot," "I'm usually aware of my appearance"). Eighteen items were phrased so that a higher score represented higher self-consciousness, and three items were worded so that lower scores reflected higher self-consciousness. For the latter items each score was subtracted from the maximum rating of 5. The scores for each subject were then summed over the 21 items (minimum = 0, maximum = 105), such that higher scores represented greater self-focused attention. The average score for all subjects was 64.72 ($SD = 11.81$). A median split was employed to classify subjects as high or low SCs (M for high SCs = 73.9, $SD = 6.56$; M for low SCs = 54.87, $SD = 7.46$). As expected, SE and self-consciousness were negatively related, $r(110) = -.30$, $p < .01$.

Concept formation task. The task was the same one used in Study 1.

Procedure

As in Study 1, subjects were told that the study would consist of several parts. In the first part they were taken to a small cubicle and asked to complete the SE and self-consciousness inventories. Afterwards they were led to another cubicle to perform the concept formation task. When the instructions and practice trial were completed, the experimenter introduced the focus-of-attention manipulations. In the two self-focus conditions, subjects were told:

> One more point. Since we are interested in how people go about forming concepts, the experimenter will be watching you as you are working

[3] The content of 2 items from this 23-item scale was very closely related to several procedural aspects of this study. Specifically, they were, "One of the last things I do before I leave my house is look in the mirror," and "I have trouble working when someone is watching me." To prevent undue suspicions from arising, these items were deleted from the questionnaire.

Table 2
Task Performance in Relation to Self-Esteem, Study 2

Self-focus	Task focus	Self-esteem: High *n*	High *M*	High *SD*	Medium *n*	Medium *M*	Medium *SD*	Low *n*	Low *M*	Low *SD*
Present	Present (combined)	7	4.43	2.56	9	2.00	1.76	10	4.40	3.20
	Absent (mirror only)	6	2.50	2.63	14	3.93	2.40	9	7.22	5.81
Absent	Present (task only)	13	3.00	3.04	8	2.88	1.69	8	1.75	1.20
	Absent (control)	11	4.18	1.99	7	3.86	1.81	10	3.60	2.15

Note. Performance was measured by errors. Scores ranged from 0 to 20. Thus, the higher the score, the poorer the performance.

on the task. Also, a mirror will be placed in front of you, making it easier for the experimenter to observe your behavior more closely.

With that, the experimenter placed the large mirror directly in front of the subject. In the two task-focus conditions, subjects were given the same task-focus instructions used in Study 1. Essentially, subjects were randomly assigned to one of four focus-of-attention treatments: (a) mirror condition—subjects were only exposed to the mirror manipulation; (b) task condition—subjects were only exposed to the instructions designed to increase task-focused and decrease self-focused attention; (c) combined condition—subjects received the task-focus instructions first, followed by the introduction of the mirror; and (d) control condition—subjects received neither attentional focus manipulation. As in Study 1 the experimenter was not aware of the subjects' SE or self-consciousness scores.

After completing the task subjects made ratings of their attentional focus and anxiety while performing the task. In addition, they were asked to write their hypotheses and suspicions about the experiment, none of which was related to the true purpose of the study. Finally, all participants were fully debriefed.

Results and Discussion

Performance

Performance in relation to self-esteem. A preliminary t test yielded no effect as a function of sex of subject. Thus, all data were analyzed with a three-factor unweighted-means analysis of variance.[4] The summary data for this measure are presented in Table 2. The analysis revealed a significant main effect for task-focus instruction, $F(1, 100) = 3.94$, $p < .05$, with subjects performing better when instructed to focus on the task. Although the SE × Task Focus interaction was not significant ($p < .15$), simple effects analyses revealed that the task-focus instructions only had a significant impact on the low SEs, $F(1, 100) = 5.52$, $p < .025$. High SEs were unaffected by the task-focus instructions ($F < 1$), and medium SEs only marginally benefited from being told to focus on the task ($p < .20$). As additional evidence that primarily low SEs were aided by the task-focus instructions, there was a marginal *inverse* relationship between SE and performance in the no-task-focus conditions, $F(2, 100) = 2.36$, $p < .10$, whereas no such tendency appeared in the task-focus conditions.

The only other significant effect to emerge was a SE × Self-Focus interaction, $F(2, 100) = 3.93$, $p < .025$. Simple effects analyses revealed that only the performance of the low

[4] As in Study 1 the SE scores (within each SE level) did not differ by condition. Also, two experimenters (one male and one female) collected the data in this study. A preliminary t test showed that subjects made more errors in the presence of the female experimenter, $t(110) = 2.56$, $p < .025$. However, there was no Sex of Subject × Sex of Experimenter interaction. Moreover, since the experimenters ran approximately equal proportions of subjects in each condition, the data were collapsed across the experimenter variable.

Table 3
Task Performance in Relation to Self-Consciousness, Study 2

Self-focus	Task focus	Self-consciousness: High *n*	High *M*	High *SD*	Low *n*	Low *M*	Low *SD*
Present	Present (combined)	11	3.64	3.25	15	3.53	2.50
	Absent (mirror only)	13	7.08	5.01	16	2.69	1.86
Absent	Present (task only)	18	3.00	2.56	11	2.00	1.86
	Absent (control)	16	4.00	1.50	12	3.75	2.55

Note. Performance was measured by errors. Scores ranged from 0 to 20. The higher the score, the poorer the performance.

SEs was adversely affected by the mirror, $F(1, 100) = 9.95$, $p < .01$. Medium and high SEs performed equally well in the self-focus and no-self-focus conditions. In addition, only a relationship between SE and performance was observed in the self-focus conditions, $F(2, 100) = 4.68$, $p < .01$, with low SEs performing significantly worse than medium and high SEs (who did not differ). In the no-self-focus conditions, there was a nonsignificant ($F < 1$) inverse relationship between SE and performance.

Performance in relation to self-consciousness. Summary data for this analysis are presented in Table 3. The analysis of variance revealed a significant main effect for self-consciousness, $F(1, 104) = 6.68$, $p < .025$, with high SCs making more errors than low SCs. A significant triple interaction, $F(1, 104) = 5.27$, $p < .025$, revealed that high SCs did particularly worse than low SCs in the mirror condition.

Of course, the main effect for task focusing was still present, $F(1, 104) = 5.96$, $p < .025$. Moreover, simple effects analyses showed that only the high SCs benefited from the task-focus instructions, $F(1, 104) = 8.21$, $p < .01$, paralleling the earlier findings for low SEs. The performance of the low SCs (like that of the high SEs) was not affected by the task-focus instructions.

Fenigstein et al. (1975) reported that the self-consciousness scale consisted of three separate factors: private self-consciousness, public self-consciousness, and social anxiety.[5] They reported that

> Private self-consciousness was concerned with attending to one's inner thoughts and feelings, public self-consciousness was defined by a general awareness of the self as a social object that has an effect on others, and social anxiety was defined by a discomfort in the presence of others. Public and private self-consciousness refer to a *process* of self-focused attention; social anxiety refers to a *reaction* to this process. (p. 523)

Accordingly, subjects were classified as high or low, with a median split for each of these three components of self-consciousness. Three three-factor analyses of variance were performed, with private self-consciousness, public self-consciousness, social anxiety, and the two focus-of-attention factors as independent variables. Interestingly, individual differences in private and public self-consciousness produced no main effects and did not interact with either of the attentional focus manipulations. However, subjects high in social anxiety (high SAs) performed significantly worse than low-social-anxiety participants (low SAs), $F(1, 104) = 6.61$, $p < .025$. Simple ef-

[5] Although Turner et al. (1978) reported negative correlations between SE and each component of self-consciousness, only a correlation between SE and social anxiety was obtained in the present study, $r(110) = -.54$, $p < .01$.

Table 4
Self-Focused Attention Index, Study 2

Self-focus	Task focus	Self-esteem: High *n*	High *M*	High *SD*	Medium *n*	Medium *M*	Medium *SD*	Low *n*	Low *M*	Low *SD*
Present	Present (combined)	7	37.14	24.87	9	19.11	25.58	10	39.10	26.22
	Absent (mirror only)	6	12.17	31.32	14	24.14	28.05	9	46.00	20.99
Absent	Present (task only)	13	28.15	32.15	8	23.50	26.46	8	20.25	18.72
	Absent (control)	11	27.64	39.77	7	4.57	25.98	10	39.80	26.68

Note. Index was summed over four questions. Scores ranged from −31 to 92, with higher scores reflecting greater self-focused attention.

fects analyses demonstrated that this was particularly true in the self-focus conditions, $F(1, 104) = 6.92$, $p < .025$. When the mirror was not present, high and low SAs did not reliably differ, $F(1, 104) = 1.01$. In addition, a triple interaction effect emerged, the nature of which was somewhat unexpected. Specifically, it was only in the control condition that high SAs did not make more errors than low SAs, $F(1, 104) = 4.42$, $p < .05$.

Focus-of-Attention Manipulation Checks

Subjects completed the following items on the postexperimental questionnaire (once again, all questions were completed on 41-point scales, with higher scores representing greater endorsement of the statement): "*While you are completing the task,* (a) how self-conscious did you feel? (b) How much were you aware of the experimenter's presence? (c) How much did you find yourself thinking about how well or how badly you seemed to be doing? and (d) How much did you find yourself completely concentrating on the task and nothing else? That is, how much would you say you were concentrating on the task to the exclusion of any other thoughts?" All items correlated with Item 1, the most direct measure of self-consciousness ($r_{1 \text{ and } 2} = .52$; $r_{1 \text{ and } 3} = .40$; $r_{1 \text{ and } 4} = -.30$; $df = 110$; $p < .01$ in all cases). Therefore, a self-focused attention index was computed for each subject by summing Items 1, 2, and 3 and subtracting Item 4. Higher scores corresponded to greater amounts of self-focused attention.

A three-factor unweighted-means analysis of variance was performed, for which the summary data can be found in Table 4. From inspecting the data one finds that the scores tend to be aligned with the error data presented in Table 2. The only anomalous finding occurred in the medium SE–control condition. There the self-focused attention scores were unusually low and not at all consistent with the error data observed in that cell. The only significant effect to emerge was a main effect for SE, $F(2, 100) = 3.37$, $p < .05$, with low SEs most and medium SEs least self-focused. However, several simple effects paralleled those found for the performance data. For example, in the no-task-focus conditions low SEs were considerably more self-focused than medium and high SEs, $F(2, 100) = 4.51$, $p < .025$. In the task-focus conditions, there were no differences between SE groups. Also, in the self-focus conditions, low SEs were marginally more self-focused than medium or high SEs, $F(2, 100) = 2.52$, $p < .10$. No such trend emerged in the no-self-focus condition.

Additional evidence of the success of the task-focus variable on the low SEs stems from the results on the measure of task-focused attention (Item 4). Just as the performance data showed that primarily low SEs were af

fected by the task-focus factor, the analyses on this measure revealed that the low SEs were most influenced by this manipulation. While the SE × Task Focus interaction was only a trend ($p < .11$), simple effects analyses showed that in the no-task-focus conditions, low SEs were considerably less task focused than medium and high SEs, $F(2, 100) = 3.40$, $p < .05$, whereas all three groups were equally task focused in the task-focus conditions ($F < 1$). Low SEs also tended to be more task focused in the task-focus than in the no-task-focus conditions, $F(1, 100) = 3.34$, $p < .07$, whereas medium and high SEs were not (both Fs < 1).

As further evidence of the role of attentional processes on performance, there was a significant correlation between subjects' scores on the self-focused attention index and the number of errors they committed, $r(110) = .32$, $p < .01$.

General Discussion

Summary and Replications

Both studies demonstrated that (only) the performance of the low SEs was quite malleable across conditions. In Study 2 the self-focusing stimulus caused low SEs to perform worse than (a) medium and high SEs who were exposed to the same stimulus and (b) low SEs who were not exposed to the mirror. In Study 1 low SEs only performed more poorly than high SEs in the presence of the self-focusing stimuli. These data replicate Brockner and Hulton (1978) and Shrauger (1972) by showing that self-focusing stimuli (operationalized differently here than in the aforementioned studies) can exacerbate or activate performance decrements for low SEs.

Alternatively, task focusing seemed to have positive effects primarily for the low SEs. In Study 2 the task-focus instructions caused low SEs to perform better than low SEs who were not provided with such instructions, whereas medium and high SEs were unaffected by this manipulation. In Study 1 the internal analysis showed that low SEs who reported high levels of task concentration made significantly fewer errors than low SEs whose task concentration was low. That analysis also showed that high SEs did equally well, regardless of their task concentration level. Both studies thus confirm Brockner and Hulton's (1978) finding that low SEs especially benefit from increased task-focused attention. However, there are some important differences between the present results and Brockner and Hulton's data that should be made explicit. Brockner and Hulton discovered that low SEs made significantly fewer errors than high SEs when both groups were instructed to focus on the task. Low SE–task condition subjects, however, did not perform significantly better than low SEs in their control condition, although the means were in that direction. In the present studies the finding that low SEs performed better than high SEs when task focusing was high was not replicated (i.e., in the task condition in Study 2 and the internal analysis of SE and task concentration in Study 1), although the means were in that direction in both studies. However, unlike Brockner and Hulton, both of the studies reported here demonstrated that low SEs who were task focused performed significantly better than less task-focused low SEs.

That the self-focusing and task-focusing stimuli generally produced replications of previous results is all the more striking given the differences in subject populations. As suggestive evidence of the heterogeneity of the samples, the subjects in the present Study 2 overall made 71% more errors than Brockner and Hulton's subjects, while the Study 1 sample made 32% more errors. However, in spite of these *overall* performance differences, the relative differences in performance *between* conditions were in most cases remarkably consistent across all three studies.

Extensions

The combined conditions, which were extensions of the Brockner and Hulton (1978) study, produced inconsistent results. The low SEs' performance in Study 2 demonstrated that when the task-focus instructions work they can actually neutralize the effects of the mirror. From the low SE column of Table 2 it

can be seen that *relative to the control condition,* performance was impaired in the mirror condition and enhanced in the task condition. The low SEs' performance in the combined condition, however, was nearly identical to that found in the control condition. It is interesting that the task-focus instructions could functionally neutralize the mirror, given the relative *objective* salience of the two stimuli. That is, the task-focus instructions consisted of several sentences that were only read to subjects right before they started to work on the task. The large mirror, however, was a very salient self-focusing stimulus that remained present throughout the course of the experiment. One could reasonably argue that the possible ameliorating effects of the task-focus instructions were provided a fairly conservative test when combined with the omnipresent mirror. That the instructions actually neutralized the mirror suggests their potential utility for low SEs in situations that are likely to cause high self-consciousness, poor performance, and perhaps exacerbated low SE.

Of course, the above remarks must be tempered by the combined condition results found in Study 1. However, given that the task-focus instructions produced no beneficial effects for low SEs when administered in isolation (i.e., in the task condition of Study 1), it is perhaps not surprising that they were ineffective when used in conjunction with the mirror and video camera.

Attentional Focus and Performance

One weakness of the Brockner and Hulton (1978) study was its failure to provide highly convincing evidence that the low SEs' performance was influenced by attentional processes. Fortunately, there is now considerable evidence to suggest that for low SEs, (a) the manipulations had their intended effects on attentional focus (except for the task-focus instructions in Study 1) and (b) attentional focus influenced performance. First, both studies showed that self-focusing stimuli had their most pronounced effects on the self-focused attention of low SEs. Manipulation checks from Study 2 (see Table 4) showed that when the data from the mirror and combined conditions were taken together, low SEs were more self-focused than medium and high SEs. The data from Study 1 also revealed that low SEs were more self-focused than high SEs in the presence of the mirror and video camera.[6] Second, there was evidence in Study 2 that the task-focus instructions reduced the low SEs' self-consciousness and increased their task-focused attention. Specifically, when subjects were not told to task focus, low SEs were significantly more self-conscious and less task focused than medium and high SEs. However, when subjects were instructed to concentrate on the task, there were no self-focusing or task-focusing differences between the three SE groups.

Given that the manipulations generally had their desired effects, what evidence was there that attentional focus affected performance? First, recall that in Study 2 there was a significant correlation between subjects' scores on the self-focused attention index and the number of errors they committed. Furthermore, from Study 2 the relationships between the individual difference measure of self-consciousness, the attentional manipulations, and performance were particularly illuminating. As stated earlier, if the performance of the low SEs in the various conditions is related to their higher self-consciousness, then one should find similar performance data for low SEs and high SCs, and for high SEs and low SCs. Both predictions received firm support. Like low SEs, *only* high SCs (a) were impaired by the self-focusing stimulus, particularly in the mirror condition, and (b) improved when instructed to task focus.

In Study 1 the task-focus manipulation did not have its desired effect on the low SEs' focus of attention. Given the present position that attention influences performance, it is not surprising that the task-focus instructions had no appreciable effect on their performance. Therefore, the most parsimonious explanation of the null effect of the task-focus

---

[6] These data serve to extend Carver and Scheier's (1978) recent verification that mirrors cause increased self-focused attention. That is, their hypothesis would seem especially true for low SE individuals.

instructions on the low SEs' performance may be the failure of the manipulation to influence attention as intended, rather than the ego involvement hypothesis posed earlier. Note that in studies showing independent evidence of the task-focus instructions' effect on the low SEs' attention (Study 2; Brockner & Hulton, 1978), the performance of the low SEs improved significantly. Moreover, even when the task-focus instructions did not influence the low SEs' attention (Study 1) the internal analysis suggested that attentional factors affected their performance.

Self-Esteem, Attentional Focus, Anxiety, and Performance

If the low SEs' attentional focus influenced their performance, one still needs to consider the theoretical bases for this relationship. Two hypotheses were proposed earlier. First, if low SEs are too self-preoccupied, they simply will not be able to devote adequate attention to the task. Second, self-focused attention may be especially anxiety provoking for low SEs, leading to performance decrements on complex tasks like the one used in the present studies. With no attempt to discount the first possibility (indeed, the two may be complementary rather than competing hypotheses), evidence from these and other studies suggests that (a) self-focusing stimuli increased the low SEs' anxiety in both studies, whereas the task-focus instructions decreased their anxiety in Study 2, and (b) anxiety, in turn, mediated task performance.

Low SE, self-focused attention, and anxiety. On theoretical grounds there is good reason to believe that the self-focusing stimuli increased the low SEs' anxiety. It seems reasonable that the low SEs entered the test situation with higher levels of anxiety than high SEs. Indeed, researchers have consistently discovered inverse relationships between SE and general or test anxiety (Crandall, 1973). Moreover, recent research by Scheier and Carver (1977) showed that self-focused attention serves to intensify an individual's affective or emotional experience. Thus, it would appear that low SEs should have become even more aware of their anxiety when self-focused. In fact, both studies showed that low SEs reported greater anxiety than high SEs in the presence of self-focusing stimuli.[7] In Study 2 this tendency was expressed as a SE × Self-Focus interaction, $F(2, 100) = 3.32$, $p < .05$, such that in the self-focus, but not in the no-self-focus, conditions there was an inverse relationship between SE and anxiety. In Study 1 the t test showed that low SEs were also more anxious than high SEs in the video–mirror and combined conditions, $t(57) = 1.61$, $p < .06$, one-tailed, but not in the absence of the self-focusing stimuli (task condition, $t < 1$).

Furthermore, recall that Fenigstein et al.'s (1975) social anxiety subscale measures the extent to which people become anxious when self-aware. As additional evidence of the self-focused attention – anxiety link for low SEs, there was a pronounced inverse correlation between SE and social anxiety in Study 2 ($r = .54$).[8]

Self-focused attention, anxiety, and performance. There is also evidence that the anxiety that results from self-focused attention impaired performance on the task used in the present studies. Specifically, it was found that in the self-focus conditions in Study 2, subjects high in social anxiety performed significantly worse than low SAs. However, in the no-self-focus conditions, high and low SAs did not differ. Furthermore, test anxiety researchers (Geen & Gange, 1977; Wine, 1971) have reported that the presence of an audience produces additional performance decrements for highly test-anxious subjects. Given that audiences increase self-focused attention (Carver & Scheier, 1978), it is possible that they increased the already high anxiety awareness level of test-anxious

---

[7] Subjects were asked, "While you were completing the task, how anxious did you feel?" Their answers were recorded on 41-point scales.

[8] While SE and social anxiety are inversely related, the nature of the anxiety produced by the low SEs' self-focused attention is still unclear. One possibility is that the anxiety is due to evaluation apprehension. This interpretation seems plausible, given that subjects high in social anxiety seem to be more concerned or worried about being evaluated by others (Turner, 1977).

subjects (Scheier & Carver, 1977), leading to additional performance decrements.

Just as the self-focusing stimuli seemed to intensify the perceived anxiety levels of low SEs, it is possible that the task-focus instructions reduced felt anxiety. In Study 2 low SEs in the task condition did report lower levels of anxiety than low SE–control condition subjects, $t(16) = 2.26$, $p < .05$, two-tailed. As already noted, low SE–task subjects made fewer errors than low SE–controls. Moreover, the test anxiety literature shows that manipulations designed to increase task-focused and decrease self-focused attention have caused dramatic improvements in the performance of highly test-anxious subjects (Sarason, 1958, 1973, 1975). It may be that their performance increments are accompanied or even caused by decreases in their usually overinflated levels of felt anxiety.

Conclusion

The present studies generally confirm the hypothesis that the task performance of low SEs is inversely related to their self-focused attention. To address an important practical issue, future investigators should consider the effect of the low SEs' performance on their subsequent SE. The implication set forth earlier was that subsequent SE should covary with task performance. However, the relationship is undoubtedly more complex. For example, how much performance improvement is necessary to bolster the self-evaluation of low SEs? How long lasting are such effects? In short, under what conditions will the low SEs' performance affect their subsequent SE? To address an important theoretical issue, future researchers should provide additional evidence of the influence of attentional processes on performance. A promising technique was recently employed by Diener and Dweck (1978), who unobtrusively assessed their subjects' task-focusing and self-focusing behaviors.

Effects of Contrast and Generalization on the Attitude Similarity – Attraction Relationship

John J. Seta, Lenny Martin, and George Capehart
University of North Carolina at Greensboro

An experiment was performed examining the phenomena of contrast and generalization within the attitude similarity – attraction paradigm. Subjects read of the attitudes of two strangers (A and B) whom they had met and who had both initially agreed with these subjects on 50% of a number of topics. After a brief period of time, each subject again met the two strangers. During this second meeting, Stranger A continued to agree with the subject at a 50% rate, whereas Stranger B agreed with the subject at a 100% rate. In one condition, the two strangers were depicted as members of the same group, and in a second condition, the two strangers were depicted as members of different groups. The results indicated that after the second meeting, there was less of a difference between the attractiveness of Strangers A and B in the same-group condition compared to the different-group condition. In addition, within the different-group condition, Stranger A was liked less after the second meeting than after the first meeting, whereas within the same-group condition, Stranger A was liked more after the second meeting than after the first meeting. These results support the notion that the effects of contrast are accentuated when two individuals being rated are distinct entities (members of different groups), whereas generalization is accentuated when the two individuals are not distinct entities (members of the same group). The above results are interpreted within the Byrne–Clore reinforcement affect model.

In the area of attraction, a great deal of research has supported the notion that attitude similarity affects attraction (e.g., Byrne, 1969, 1971; Byrne & Nelson, 1965; Clore & Baldridge, 1968; Griffitt, 1971; Schachter, 1951). The effects of attitude similarity on attraction can best be described as a "positive linear function of the sum of the weighted similar attitudes divided by the total number of weighted similar and dissimilar attitudes" (Byrne, 1971, p. 71). The Byrne–Clore reinforcement affect model (e.g., Byrne & Clore, 1970) has been the most parsimonious account of the attitude similarity – attraction paradigm. Briefly, they propose (Byrne, 1971) that the affective response elicited by an individual (X) "is a positive linear function of the sum of the weighted positive reinforcements associated with X divided by the total number of weighted positive and negative reinforcements associated with X" (pp. 279–280).

The present article deals with how the weight or value of a positive reinforcer or punisher associated with X is affected by the presence of a second individual. That is, the attractiveness of a particular individual should depend not only on the reinforcers (e.g., agreements) and punishers (e.g., disagreements) obtained from that particular individual but also on the reinforcers and punishers obtained from other individuals in the situation. A situation in which an individual meets two strangers is briefly depicted. Individual X simultaneously meets two strangers (Stranger A and Stranger B) who both initially agree with X on 50% of a number of topics. After

The present investigation was partially supported by a grant from the University of North Carolina at Greensboro.

a brief period of time, X again meets these two strangers and discusses a number of different, yet equally important, topics. During this second meeting, Stranger A continues to agree with X at a 50% rate, whereas Stranger B now agrees with X on 100% of the topics.

Opposing Predictions

The question that can be asked is "Would the attractiveness of each of the strangers depend on the presence of the other?" Further, would Stranger A be liked more by X after their first or after their second meeting? Likewise, would Stranger B be liked more after their second meeting? Predictions concerning this question can be derived from two sources. The first is the phenomenon of contrast (e.g., Helson, 1964). Since contrast occurs when the differences between two stimuli are accentuated, one would predict that X would like Stranger A less after their second rather than their first meeting, even though Stranger A's proportion of agreements has not changed. Stranger A's rate of agreement after the second meeting should seem less valued, since Stranger B has increased his or her agreements from 50% to 100%. In contrast, Stranger B should be liked more after the second meeting, since not only has the rate of agreement increased but the rate has also increased relative to that of Stranger A. Experiments by Mascaro and Graves (1973) and Griffitt (1971) support the notion of a contrast effect within the attitude similarity–attraction paradigm. Mascaro and Graves (1973) found that a second stranger's attraction was affected by the first stranger's rate of agreement.[1] That is, the second stranger was liked less as the first stranger's rate of agreement increased relative to that of the second stranger.

An opposing prediction can be made from the phenomenon of stimulus generalization. Since generalization occurs when different stimuli evoke a common response, one would predict that X would like Stranger A more after their second meeting than after their first meeting. Stranger B's 100% agreement rate should positively affect the value of Stranger A's 50% rate, since A and B's agreement rate might be averaged if the two individuals are perceived as a unit. An experiment by Wyant, Lippert, Wyant, and Moring (1977) seems to support the concept of generalization within the attitude similarity–attraction paradigm. They found that the effects of one stranger's evaluation generalized to a second stranger. In this experiment, the second stranger was depicted as being similar to the first.

Contrast and Generalization

The phenomena of contrast and generalization may occur under somewhat different conditions. Contrast should predominate when the individuals being judged are seen as distinct entities or members of different groups, whereas generalization should predominate when the individuals being judged are not distinct, being members of the same group. In essence, the attractiveness of a particular individual should depend not only on the reinforcers and punishers obtained from that particular individual but also on the reinforcers and punishers obtained from other individuals. If there is an association, then the affective response associated with each of the individuals should generalize. That is, there should be a tendency to average the reinforcers obtained from each individual and therefore minimize differences between them. However, if the two individuals come from different groups, a contrast effect should be pronounced. That is, the reinforcers and punishers and, hence, the affective response associated with one individual should be compared to the affective response associated with the second individual. Given that there are differences in the absolute magnitude of rein-

[1] In this study, subjects first met one stranger and then at some later time met a second stranger. Specifically, their results supported the notion of what can be labeled *successive contrast*. However, their results do not support the existence of what can be labeled *simultaneous contrast*. Simultaneous contrast would be supported if the subjects met the two strangers simultaneously and a contrast effect was obtained. The present experiment tests the notion of simultaneous contrast within the attitude similarity–attraction paradigm.

forcement obtained from the two individuals, a contrast effect would accentuate these differences.

The present experiment was performed in an attempt to answer the following questions: First, does the evaluation that is given to an individual depend on the percentage of agreements (rewards) given by a second individual? Second, under what conditions would a contrast effect be accentuated and under what conditions might a generalization effect be accentuated? In this experiment a subject initially meets two strangers (A and B) who independently agree with the subject on 50% of the topics. After rating both strangers, the subjects were presented with additional attitudes of the two strangers on six new topics and again were asked to independently rate the attractiveness of the two strangers. During this second meeting, Stranger A continued to agree with the subject at a 50% rate, whereas Stranger B now agreed with the subject at a 100% rate. In the first condition (different-group condition), Strangers A and B were depicted as members of different groups (one stranger was a math major, and the other was a drama major), whereas in a second condition (same-group condition), both strangers were depicted as members of the same group. (Both strangers were math majors or both strangers were drama majors.) As earlier mentioned, the effects of contrast should be accentuated when an individual concentrates on the distinctive properties of others (different-group condition), whereas generalization should be accentuated when an averaging of differences is made (same-group condition). That is, after the second meeting there should be less of a difference between the attractiveness of Strangers A and B in the same-group condition compared to the different-group condition. Differences should be accentuated in the different-group condition (contrast predominates) and minimized in the same-group condition (generalization predominates).

Method

Subjects

Thirty-six students (31 females and 5 males) from two junior-level psychology classes were randomly assigned to either the same- or different-group condition. There were 18 subjects (15 females and 3 males) in the different-group condition and 18 subjects (16 females and 2 males) in the same-group condition. Subjects were run in groups. One group consisted of 24 subjects (12 in the same-group condition and 12 in the different-group condition), and the second group consisted of 12 subjects (6 in the same-group condition and 6 in the different-group condition). All subjects volunteered their participation.

Experimental Design

A one between (same or different) and two within [Persons A or B and trials (first or second meeting)] repeated measures analysis of variance was performed. In the same-group condition, Strangers A and B were depicted as either both math or both drama majors, whereas in the different-group condition one stranger was depicted as a math major and the other as a drama major. The order of depiction was counterbalanced.

Procedure

Consistent with the phantom–other procedure (e.g., Byrne & McGraw, 1964), subjects first filled out a standard questionnaire defining their attitudes (e.g., Byrne & Nelson, 1965). Approximately 3 weeks after filling out the standard questionnaire defining their attitudes, all subjects were presented with typed instructions and the purported attitudes of Strangers A and B. After reading the instructions, subjects in both conditions read of the attitudes of Strangers A and B (both agreed on 50% of the six topics) and were then asked to rate each stranger separately. All subjects were asked to respond to three questions. Each question contained a 7-point scale, where 1 corresponded to like and 7 corresponded to dislike. The three questions were: (a) How much would you enjoy working further with this person? (b) How much did you like the stranger? and (c) How much would you like to continue a relationship with the stranger? After rating the strangers, all subjects were presented with additional attitudes of Strangers A and B. This time Stranger A agreed with the subject on 50% of the six new topics, whereas Stranger B agreed with the subject on 100% of the six new topics. All subjects were then asked by typed instructions to again rate Strangers A and B.

As a manipulation check, a preexperimental questionnaire was given to 12 subjects who were similar in academic standing to the subjects used in the present study. Using only information that was given to them by the experimenter, they were asked to answer two questions: (a) Who do you feel are more similar, two math majors or a math major and a drama major? (b) Who do you feel are more similar, two drama majors or a math major and a drama major? The phrasing of the above questions was counterbalanced. All subjects felt that the two math

majors were more similar than the math major and the drama major and that the two drama majors were more similar than the math major and the drama major. A postexperimental interview was also given to 10 subjects. They were asked if they had read the entire instructions and attitudes of the strangers. In addition, they were asked if they knew that they were rating two different individuals and if they remembered if they had rated two individuals who had the same major or two individuals who had different majors.

Results and Discussion

A between (same or different)–within [Persons A or B and trials (first or second meeting)] repeated measures analysis of variance was performed. Since all three measures were nearly identical, the total of all three measures was used in the analysis. (See Table 1 for the means of each of the experimental conditions.) The analysis revealed a significant Group (same or different) × Person (Strangers A or B) × Trials interaction, $F(1, 34) = 55.30$, $p < .001$; a Person × Trial interaction, $F(1, 34) = 83.99$, $p < .001$; and a Group × Person interaction, $F(1, 34) = 5.93$, $p < .05$. In addition, consistent with the Byrne–Clore (1970) framework, a person main effect, $F(1, 34) = 87.32$, $p < .001$, and a trials main effect were obtained, $F(1, 34) = 106.43$, $p < .001$. All subjects that were asked stated that they had read all of the instructions and the attitudes of the strangers. In addition, the subjects were aware of whom they had rated (e.g., two math majors).

Results Supporting Contrast and Generalization

To interpret the significant interactions a Tukey (a) test was performed on all logical comparisons of paired means. (See Table 1 for a summary of the comparisons.) Within the different-group condition, Stranger A was liked less after the second meeting than after the first meeting ($p < .05$), whereas within the same-group condition, Stranger A was liked more after the second meeting than after the first meeting ($p < .05$). These results support the contrast–generalization interpretation, since within the different-group condition, contrast should predominate, whereas in the same-group condition, generalization should predominate. In the different-group condition, Stranger A's 50% rate of agreement should be contrasted to Stranger B's 100% rate, resulting in a reduced level of attraction for Stranger A. Within the same-group condition, Stranger B's 100% agreement rate should generalize and positively affect the value of Stranger A's 50% rate.

Although the comparisons did not reach significance, after the second meeting Stranger B was liked somewhat more in the different-group condition than in the same-group condition, whereas after the second meeting Stranger A was liked somewhat more in the same-group condition than in the different-

Table 1
Attraction Score Means for Each Condition

Person A		Person B	
Trial 1	Trial 2	Trial 1	Trial 2
Different-group condition			
11.50	13.61	13.55	7.66
Same-group condition			
13.33	11.55	12.61	10.00

Note. The higher the score, the less the attraction. Range of scores is 3–21. The following is a summary of the significant logical comparisons among paired means using the Tukey (a) test with the level of significance set at .05. A pooled error term was employed as suggested by Winer (1971). For comparisons between Trials 1 and 2 for Person A or Person B, the critical difference was 1.43. In the different-group condition, Person A was liked significantly less after the second than after the first meeting. In the same-group condition, Person A was liked significantly more after the second than after the first meeting. In both the same and different conditions, Person B was liked significantly more after the second than after the first meeting. None of the comparisons between the different- and same-group conditions reached significance. The critical differences for these comparisons was 4.75. For comparisons between Persons A and B within either the different- or same-group conditions, the critical difference was 1.26. During the first meeting, Person A was liked significantly more than Person B in the different-group condition. During the second meeting, Person B was liked significantly more than Person A in both the same- and different-group conditions.

group condition. This result is consistent with a contrast–generalization interpretation. In the different-group condition, contrast should predominate, whereas in the same-group condition, generalization should predominate.

Stranger B was liked more after the second meeting than after the first meeting in both the same- and different-group conditions ($p < .05$). In both the same-group and different-group conditions, Stranger B's attraction should have increased from the first to the second meeting because of Stranger B's increase in agreement rate (50%–100%). However, the increase in attraction from the first to the second meeting was greater for B in the different-group than in the same-group condition. (In the different-group condition the difference was 5.89, whereas in the same-group condition the difference was 2.61.) This should have been the case, since in the same-group condition, generalization should predominate, whereas in the different-group condition, contrast should predominate. In the same-group condition, Stranger B's attraction might have been lessened due to B's association with A (A's rate is lower than B's); in the different-group condition, Stranger B's attraction should have increased because of A's low rate of agreement. Finally, after the second meeting, there was less of a difference between the attractiveness of Strangers A and B in the same-group compared to the different-group condition. An analysis of variance on difference scores revealed that after the second meeting, there was less of a difference between the attractiveness of Strangers A and B in the same-group condition (28 difference) compared to the different-group condition (107 difference), $F(1, 34) = 67.9$, $p < .001$. This should have been the case, since differences should be accentuated in the contrast condition and minimized in the generalization condition.

The above results support the notion that the attractiveness of a particular individual should depend not only on the reinforcers and punishers obtained from that particular individual but also on the reinforcers and punishers obtained from other individuals. In addition, the magnitude of the reinforcers and punishers should depend on whether there is or is not a strong commonality between the two individuals. If there is an association, then the affective response associated with each of the individuals should generalize—There should be a tendency to average the reinforcers obtained from each individual. However, if the two individuals are perceived as distinct entities, a contrast effect should be pronounced.

Consensual Validation

As one can see from Table 1, after the first meeting, subjects liked Stranger A more than Stranger B in the different-group condition ($p < .05$). Although no a priori predictions were made concerning subjects' first ratings of Strangers A and B (both agreed with the subject on 50% of the topics), these results are quite interesting and explicable within Byrne & Clore's (1967) theoretical framework if one assumes that a 50% agreement rate is below that which the subjects are accustomed to receiving. Byrne and Clore (1967) argued that a possible reason why increasing rates of agreement result in increments in attraction is that attitudinal agreement supplies an individual with consensual validation. Hence, there should be greater invalidation the greater the number of groups disagreeing with the subject. Due to the above, subjects in the different-group condition should like Stranger B less than Stranger A because Stranger B's general disagreement results in a greater degree of consensual invalidation. Further, since the weight of consensual invalidation is greater for B than for A, there should be a greater probability of discounting the first stranger's general disagreement.

In sum, the results of the present experiment support the notion that both contrast and generalization must be considered when investigating the effects of attraction. In addition, these results suggest that the probability of obtaining a generalization effect is increased as the perceived commonality between two individuals is increased. Further, the probability of obtaining a contrast effect is increased as the perceived commonality between two individuals is decreased. The pres-

ent results indicate that certain personality types should enhance the contrast effect—Individuals who concentrate on individual differences should demonstrate a pronounced contrast effect when compared to individuals who concentrate on the similarities among people.

Received June 9, 1978 ■

Notice to Authors of the *Journal of Personality and Social Psychology*

Papers submitted to the *Journal of Personality and Social Psychology* after April 1, 1979 will be considered under new policies approved by the Publications and Communications Board. Effective with the 1980 volume of the journal, the following policies will apply:

The *Journal of Personality and Social Psychology* publishes original papers in all areas of personality and social psychology. It emphasizes empirical reports but may include specialized theoretical, methodological, and review papers. Beginning in 1980, the journal will be divided into 3 independently edited sections: ATTITUDES AND SOCIAL COGNITION, INTERPERSONAL RELATIONS AND GROUP PROCESSES, and PERSONALITY PROCESSES AND INDIVIDUAL DIFFERENCES. Authors should submit manuscripts to the appropriate section editor according to the following definitions:

- ATTITUDES AND SOCIAL COGNITION includes papers on attitudes dealing with such topics as the formation or change of beliefs and attitudes, measurement of attitudes, and the relation between attitudes and behavior. Papers on social cognition deal with the formation and utilization of knowledge about the social world and embrace such topics as social and person perception, attributional processes, and information processing.
- INTERPERSONAL RELATIONS AND SOCIAL INTERACTION focuses on the interaction between two or more people. Included in this section are papers on group structure; helping and aggression; group decision making and task performance; leadership; cooperation and competition; ingroup–outgroup relations, etc.
- PERSONALITY PROCESSES AND INDIVIDUAL DIFFERENCES encourages papers on all aspects of personality psychology as traditionally defined. This includes personality assessment, measurement, structure, and dynamics. All methodological approaches will be considered.

Section editors reserve the right to redirect papers among themselves as appropriate unless an author specifically requests otherwise. Rejection by one section editor is considered rejection by all, therefore a manuscript rejected by one section editor should not be submitted to another.

Authors should prepare manuscripts according to the *Publication Manual of the American Psychological Association* (2nd edition) and the "Guidelines for Nonsexist Language in APA Journals" (Publication Manual Change Sheet 2, *American Psychologist,* June 1977, pp. 487–494). Instructions on tables, figures, references, metrics, and typing (all copy must be double-spaced) appear in the Manual. Articles not prepared according to the Manual will not be reviewed.

Manuscripts should be submitted in quadruplicate (an original and 3 copies) to the appropriate section editor. Authors should keep a copy of the manuscript to guard against loss.

Blind review is optional and must be specifically requested when a manuscript is first submitted. In those cases, authors' names and affiliations must appear only on a separate title page, included with each copy of the manuscript. Footnotes containing the identity of authors or their affiliations must be on a separate sheet.

Mailing addresses for the section editors are as follows:

Schizophrenia

Towards a New Synthesis

Edited by J. K. WING

This book provides a comprehensive and readable account of modern knowledge about schizophrenia. The authors are all recognized experts, outstanding in their various fields, and all have attempted to weigh the firm empirical findings from other approaches with the current state of research in their own specialty, rather than make extravagant theoretical or therapeutic claims. Progress in biochemistry has been made through investigations into the mode of action of certain drugs, seen to be effective: genetics, first approached through the hazardous means of twins studies, has now produced incontrovertible evidence for an inherited component in schizophrenia. But perhaps the greatest recent advances—many of them made in the UK and brought together here for the first time—concern the way in which social and psychological factors precipitate onset and relapse and influence the course of schizophrenic disorders. Implications for treatment, rehabilitation, home management and social work are discussed in full.

from Harper & Row, a humanistic perspective on psychological growth.

FRANK BARRON

The Shaping of Personality

CONFLICT, CHOICE, AND GROWTH

In this personal, humanistic introduction to the study of personality, Barron focuses on four areas: Human Design—those characteristics and potentialities which are uniquely human; Human Development—the growth of personality from conception to mature individuality; Conflict—the psychic product of man's dualistic nature; Human Selves—the study of the person as a whole, distinct from either psychoanalytic or behaviorist viewpoints. Borrowing from gestalt psychology, pragmatism, and traditional clinical approaches, Barron sees *choice* as the decisive factor in human growth.

Look UP to Dorsey in '79

Understanding Social Psychology, Revised Edition

By **Stephen Worchel,** University of Virginia and
Joel Cooper, Princeton University

This text presents both traditional and contemporary experimental research and theory with the emphasis on the active areas of research. Experimental research is placed in the context of "critical incidents" from the real world or literature to help the student understand these events. The text begins with the reaction of individuals in the formation of attitudes, change of attitudes and the attribution of characteristics to self and others and then moves toward a consideration of the individual in a more macroscopic environment. **Teacher's Manual** and **Student Workbook.** *Just Published*

Personality: Strategies and Issues, Third Edition

By **Robert M. Liebert,** State University of New York at Stony Brook
and **Michael D. Spiegler,** Providence College

This text provides an accurate, respected survey of psychological theory and research about human personality. An even-handed view is taken toward the various approaches to the subject while at the same time presenting the strengths and weaknesses of each viewpoint. All the various theories of personality are seen as growing out of four basic strategies for studying personality including: theory, research, personality assessment, and personality change. **Instructor's Manual.** *Recently published*

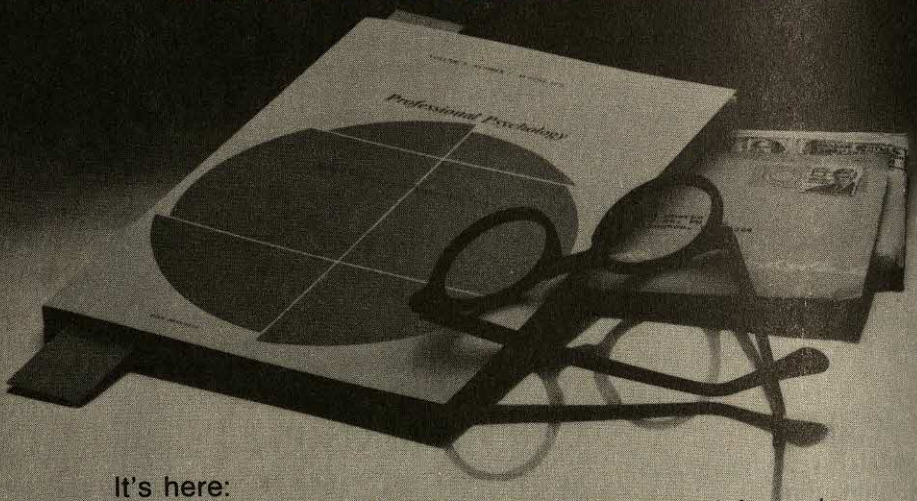
NOW: INFORMATION ABOUT THE LAW AND PSYCHOLOGY.



It's here:
Law and Professional Psychology. This special August 1978 issue of **Professional Psychology** brings you thirteen original articles full of fresh thought and constructive recommendations on the issues that vitally affect your day-to-day practice. You'll find precautions you may take to protect yourself as a professional and a plan for improving investigations of malpractice claims. Expert witness testimony, jury selection, civil commitment, confidentiality and privilege, minor's consent to treatment, and the use of psychological devices are critically examined.

Send your order today. And soon you'll receive this special issue.

Single copies of the issue are available for $5 each. All orders $25 or less must be prepaid. Make and send checks payable to:

American Psychological Association
Order Department
1200 17th Street, N.W.
Washington, D.C. 20036

Enclosed is $_____for__copies of **Professional Psychology's** special issue—Law and Professional Psychology—at $5.00 each.

Student-involving introductory texts

NEW

EXPERIENCING SOCIAL PSYCHOLOGY: Readings and Projects

Ayala Pines and **Christina Maslach,** both of the University of California, Berkeley

This integrated reader/project manual features research articles and popular readings on current topics, classical problems, and new content areas such as social pathology, ethical dilemmas of researchers, and the problems of "burn-out" among helping professionals. The introduction shows students how to read such material critically, while thoroughly class-tested projects make this material concrete by involving students in a variety of independent activities, including data collection, theoretical critiques, and group exercises.

Random House/1979/320 pages paperbound/Order Codes: 31281, 32168 (I.M.)

PERSONALITY: An Introduction

John Lamberth, Herbert Rappaport, and **Margaret Rappaport,** all of Temple University

Each chapter of this comprehensive text was written by the author with the greatest expertise and interest in the area, making the whole text completely authoritative. Every major aspect of personality study — assessment techniques, development, research, and applications — is fully covered and viewed in the light of all theoretical approaches, giving you the most comprehensive, balanced, up-to-date presentation possible.

The Journal of Personality and Social Psychology publishes original reports of research, methodology, theory, criticism, and literature review in the fields of personality and social psychology of normal processes and populations. Submitted manuscripts should delineate an important question and provide a clear answer to it. In the case of research reports, this will often require demonstration that the reported results are generalizable beyond a single research setting. Consult the editorial in the January 1976 issue (Vol. 33, pp. 1–7) for a detailed statement of policies and instructions to authors.

Manuscripts: Submit manuscripts in quadruplicate, prepared according to the *Publication Manual of the American Psychological Association* (2nd ed.). Copies should be highly legible and will not be returned to authors unless they are original typewritten copies. Mail manuscripts according to instructions on pp. 635.

Required supplementary information: Manuscripts cannot be reviewed for publication unless the author provides supplementary information in the following categories: (a) a cover letter that indicates the relation (or the lack of relation) of the submitted manuscript to other papers by the same author(s) that are currently submitted, in press, or recently published; (b) one copy of each such related paper; (c) one copy of a statement of the procedures of the research reported in the submitted manuscript in sufficient detail to serve as a guide for conduct of an exact replication; and (d) one copy of the summary tables (e.g., correlation tables, analysis of variance summaries) for the *major* analyses reported. If it appears that the supplementary materials in categories (c) or (d) might be bulky, the author should exercise judgment and restaint in selecting what to send. It is not necessary to send supplementary material that repeats verbatim manuscript content.

After a manuscript is accepted, authors will be expected to provide assurance that their data are available in unanalyzed form for reanalyses by other investigators and that their research procedures were consistent with the American Psychological Association's published principles of research ethics, except insofar as may be detailed otherwise in the manuscript.

Copyright and Permission: All rights reserved. Written permission must be obtained from the American Psychological Association for copying or reprinting text of more than 500 words, tables, or figures. Permission is normally granted contingent upon like permission of the author, inclusion of the APA copyright notice on the first page of reproduced material, and payment of a fee of $10 per page, table, or figure. Abstracting is permitted with credit to the source. Permissions and fees are waived for authors who wish to reproduce their own material for personal use; fees only are waived for authors who wish to use their own material commercially. Permission and fees are waived for the photocopying of isolated articles for nonprofit classroom or library reserve use by instructors and educational institutions. Libraries are permitted to photocopy beyond the limits of U.S. copyright law: (1) those post-1977 articles with a code at the bottom of the first page, provided the per-copy fee indicated in the code is paid through the Copyright Clearance Center, P.O. Box 765, Schenectady, NY 12301; (2) pre-1978 articles, provided that the per-copy fee stated in the Publishers' Fee List is paid through the Copyright Clearance Center, P.O. Box 765, Schenectady, NY 12301. Address requests for reprint permission to the Permissions Office, APA, 1200 Seventeenth Street, N.W., Washington, D.C. 20036.

Subscriptions: Subscriptions are available on a calendar year basis only (January through December). Nonmember rates for 1979: $60 domestic, $64 foreign, $6 single issue. APA member rate: $20. Write to Subscription Section, APA.

Change of Address: Send change of address notice and a recent mailing label to the attention of the Subscription Section, APA, 30 days prior to the actual change of address. APA will not replace undelivered copies resulting from address changes; journals will be forwarded only if subscribers notify the local post office in writing that they will guarantee second-class forwarding postage.

Reprints: Authors may order reprints of their articles from the printer when they receive proofs.

Back Issues and Back Volumes: For information regarding back issues or back volumes write to Order Department, APA.

Microform Editions: For information regarding microform editions write to any of the following: Johnson Associates, Inc., P.O. Box 1017, Greenwich, Connecticut 06830; University Microfilms, Ann Arbor, Michigan 48106; or Princeton Microfilms, Princeton, New Jersey 08540.

Published monthly in one volume per year by the American Psychological Association, Inc., 1200 Seventeenth Street, N.W., Washington, D.C. 20036. Printed in the U.S.A. Second-class postage paid at Arlington, Va., and at additional mailing offices.

Cognitive Processes in Implicit Personality Trait Inferences

Ebbe B. Ebbesen and Robert B. Allen
University of California, San Diego

The cognitive processes by which people infer whether individuals who possess one trait also possess another were examined in two reaction time experiments. Subjects took less time to affirm and more time to deny that two traits co-occurred, the greater the *semantic* similarity of the traits. As the amount of recalled evidence required to affirm that two traits co-occurred was increased by altering the nature of the co-occurrence statements, true response times increased and false response times decreased. Although it was not possible to determine whether the stored semantic "features" of a trait are locations on meaning dimensions, specific behaviors, known people characterized by the trait, or something else, the results nevertheless strongly suggest that implicit personality inferences result from a two-stage process in which the second and more detailed memory search stage is entered only if the similarity of the semantic features of the traits falls in between two task-established decision criteria.

People are willing to infer that an individual has one trait or characteristic from information about the other traits or characteristics possessed by that individual (Asch, 1946; Schneider, 1973). Inferences about the nature of someone's personality are made with relative confidence even in the absence of direct (or behavioral) indicators of many of the inferred traits (Asch, 1946; D'Andrade, 1974; Fiske, 1978; Mischel, 1968; Shweder, 1975). This tendency to infer some traits from knowledge about other traits has been termed "implicit personality theory" (Bruner & Tagiuri, 1954; Schneider, 1973). Several issues within this general topic area have received considerable research attention. Some studies have attempted to characterize the *structure* of the interrelationships among trait terms (see Rosenberg & Sedlak, 1972, for a review). Factor analysis models (e.g., Mulaik, 1964; Passini & Norman, 1966), multidimensional scaling models (e.g., Rosenberg & Sedlak, 1972), and hierarchical clustering models (Johnson, 1967) have all been explored and generally provide

This research was supported by Grant MH 26069 from the National Institute of Mental Health to the first author. Analyses of portions of the data were supported by Bell Laboratories, Murray Hill, New Jersey. Portions of the results described in this article were reported at the meeting of the American Psychological Association, San Francisco, California, August 1977. The assistance of Marie-Claire Valtz in running the first experiment is greatly appreciated.

Requests for reprints should be sent to Ebbe B. Ebbesen, Department of Psychology, C-009, University of California, San Diego, La Jolla, California 92093.

interpretable representations. Other studies have been concerned with the way groups of traits *combine* to affect the amount of another trait (e.g., likeableness) that is inferred or perceived (Anderson, 1974). Finally, some have examined the role of implicit personality theory in other phenomena, such as memory for a list of trait terms or behavior descriptions (e.g., Cantor & Mischel, 1977).

Although these various approaches to the study of implicit personality theory have yielded a wealth of evidence about the type, strength, and structure of the relationships among people's trait conceptions, little is known about the nature of the *inference processes* that allow these relationships to emerge in different tasks. There is, however, a growing body of literature within cognitive psychology that focuses on such issues—but for information sets other than trait terms. For example, in a classic study, Collins and Quillian (1969) used a binary forced-choice (true/false) decision task to study the nature of semantic memory. Subjects were asked to make true/false decisions about the assertion "A(n) *X* is a(n) *Y*," where *X* and *Y* were object and category names such as *robin* and *bird*, or *bus* and *vehicle*. They suggested that the time that subjects took to answer such questions could be used as evidence for models of the structure of semantic information, of the retrieval of that information from memory, and of the inference or decision processes that governed how that information was used in the construction of answers to such questions.

Researchers interested in implicit personality theory have required that subjects answer questions with similar formats to those used by Collins and Quillian. For example, in one method, subjects are asked to indicate the likelihood that a person who has Trait *X* also has Trait *Y* (Bruner, Shapiro, & Tagiuri, 1958; Hays, 1958; Lay & Jackson 1969). We can reformulate such questions so that they conform to the binary forced-choice paradigm used by Collins and Quillian by asking people to verify whether "a(n) *X* person is a(n) *Y* person," where *X* and *Y* are trait terms. Although these questions are not identical to the noun questions typically used in cognitive research, we can still examine the length of time it takes subjects to indicate whether a given class of objects (people, in our case) possess particular attributes (traits, in our case). The decision time data can then be used in the same way Collins and Quillian (1969) and others (e.g., Smith, Shoben, & Rips, 1974) have used them.

Although the major predictions of such decision time experiments depend on the specific nature of the search and decision processes that are proposed, it is usually the case that search processes are constructed to fit a particular theory about the structure of semantic memory. Two different structural representations that have been proposed for object categories seem most reasonable in the case of personality traits. In one view, a trait can be characterized in terms of the set of "people I have known" who possess that trait. The meaning of a trait stems from the set of person examples associated with that trait. People know what the trait term *generous* means because they can retrieve from memory one or more examples who seem to possess the trait of generosity. In other words, a set of remembered examples defines the trait term.

A second view characterizes the meaning of a trait term as a list of more elementary features. Some of these features might be locations on underlying dimensions (see Rosenberg & Sedlak, 1972) such as socially good–bad and/or dominant–submissive. Features might also be behaviors typically linked to that trait. For example, donating money to charity could be a feature of the trait of generosity. Here, the meaning of a trait term is derived from the list of basic features rather than from the sample of known people it activates in memory. These two models of the structure of personality trait terms suggest, on an intuitive basis, somewhat different inference processes for the type of binary forced-choice tasks outlined above. Let us consider these next.

Exemplar Scanning Model

If personality traits are represented in memory not as a list of more basic features

but rather as sets of persons who have the relevant characteristic (see Walker, 1975), then, when asked to verify trait co-occurrence statements (e.g., "A witty person is also generous"), people might retrieve one or more of the known persons who possess the first trait (witty) and examine this sample to determine whether the second trait (generous) is an attribute of the people in the sample. We can further assume, as Walker has done for object categories, that a "true" response will be made when a sufficient number of the person examples in the sample possess the second trait and that a "false" response will be emitted when an insufficient number of the exemplars in the sample possess the second trait. It should be emphasized that there is no need to assume that a subject considers the entire set of known people who possess the first trait. We need merely assume that a subject creates a sample, probably consisting of the most available and/or typical people in the entire set (Kahneman & Tversky, 1972; Walker, 1975). In this model, the length of time a person takes to reach a decision should increase as the number of examples that are examined increases.

Feature Comparison Model

Regardless of the intuitive plausibility of the person-exemplar model, beginning with Smith et al. (1974), several reaction time experiments, using the Collins and Quillian (1969) paradigm, have supported a somewhat different view. Specifically, people might verify assertions about object categories on the basis of the overall similarity between lists of features that the two concepts (X and Y) activate in memory. This model assumes that when the similarity of the two feature lists is above some task-established cut point, C_T, the participant responds "true." However, when the similarity of the two feature lists is below another cut point, C_F, a "false" response is made. When the similarity of the feature lists falls between these two cut points, as might happen for assertions such as "A robin is an animal" or "A dolphin is a fish," a second stage of processing is hypothesized, and therefore the time to reach a decision regarding such assertions should be longer. While Smith et al. (1974) argued that this additional processing consisted of an examination of the similarity of only the *defining* (as opposed to the most *typical*) features of the two concepts, it is sufficient for our purposes to argue that the additional processing requires that more features be examined than in the initial stage (or that the same ones be reexamined) without specifying the exact nature of the second stage. The most straightforward decision time prediction of this model is that the time to make "false" decisions should *increase* with the similarity of the two feature lists, whereas the time to make "true" decisions should *decrease*.

Effects of Quantification in Each Model

Quantification refers to the fact that we can alter an assertion by replacing "a person" with "all people" or "some people." Thus, rather than asking participants to verify the sentence "A witty person is also intelligent," we could ask them to verify the *universal* assertion "All witty people are also intelligent" or the *particular* assertion "Some witty people are also intelligent." The effects of these alterations on decision times can offer insights into the decision and search processes used in generating responses to our statements (see Meyer, 1970; Rips, 1975).

Exemplar scanning. If a participant does retrieve from memory a sample of person exemplars with the X trait and examines them to determine whether they also possess the Y trait, decision times should increase as the number of exemplars that are examined increases. Consider universal assertions. Here, participants are attempting to decide whether all Xs are Ys. It seems reasonable to expect that the participants would respond "true" only if all of the X exemplars in the retrieved sample were found to possess the Y trait. However, once the first X exemplar that did not possess the Y trait was encountered, this should provide sufficient evidence to stop the examination and respond "false." The likelihood of finding an X exemplar without the Y trait in the sample will depend on the co-occurrence of the X and Y traits in the set of known people. If every

known X exemplar possesses the Y trait (complete co-occurrence), long, "true" decision times should be found. If, on the other hand, none of the X exemplars possesses the Y traits (no co-occurrence), then the first retrieved example will always provide sufficient evidence for fast, "false" decision times. When some, but not all, of the known Xs are Ys (partial co-occurrence), then the length of time should depend on the size of the sample retrieved and the proportion of X exemplars with the Y trait that are in the retrieved sample. The greater the number of X exemplars that are examined before a negative instance is encountered, the longer the time to reach a "false" decision.[1]

It should be noted, however, that if the sample size is constant, and greater than one, all of the latter "false" decision times should be shorter than "true" decision times (because fewer examples are examined) and longer (on the average) than the "false" times for the no-co-occurrence case (since only one example needs to be examined in the latter instance). Thus, for universal assertions, participants should take the longest time to verify statements in which there is complete co-occurrence, the shortest time to negate statements in which the X and Y traits do not co-occur, and an intermediate amount of time to negate statements in which the X and Y traits co-occur for some but not all of the exemplars.

Applying similar reasoning to particular assertions predicts that participants should emit fast, "true" responses when there is complete co-occurrence, because the first example should provide sufficient evidence that at least one X exemplar has the Y trait.[2] On the other hand, long, "false" response times should be observed when there is no co-occurrence. The entire sample should be examined before the participants are sure that not even one X exemplar has the Y trait. Moderately long "false" times should result when there is partial co-occurrence, because, on the average, more than one but less than the entire sample of exemplars should be examined before a positive case is found.

Feature comparison. Rips (1975) has outlined how the feature comparison model might be affected by quantifying assertions with *all* and *some*. His argument consisted of several major points. First, he noted that the similarity of the X and Y feature lists will generally be confounded with co-occurrence relationships. The feature lists of X and Y should be most similar when there is complete co-occurrence and least similar when there is none. Second, he argued that quantification of assertions would affect the placement of C_T (but not C_F) on the feature similarity dimension. C_T should be set high (making it harder to say "true") for universally quantified sentences and moderately low (making it easier to say "true") for sentences quantified by *some*. Note that if the position of C_F does not change, then the number of sentences requiring second-stage processing should be smaller for particular than for universal assertions. The distance between C_T and C_F should be smaller, and therefore the probability of any given X–Y similarity estimate falling between them should be reduced. Finally, to make exact predictions, we must know how the similarities of the three types of trait pairs are distributed. Rips (1975) assumed that for object categories, the average similarity of Xs and Ys in which only some of the X exemplars could be classified as Y types (e.g., *mother* and *doctor*) would be closer to the average similarity of X–Y pairs in which all of the X exemplars could be classified as Y types (e.g., *mother*

---

[1] Because we are proposing that the decision is based on an examination of a *sample* rather than on all of the known persons, decision errors can be easily accounted for by this model. For example, a subject could respond "true" to a universal assertion even though only some of the known persons who possess the X trait also possess the Y trait. We need merely assume that the retrieved *sample* consisted of X exemplars, all of whom possessed the Y trait.

[2] To make this prediction we have assumed that subjects interpret the quantifier *some* to mean "at least one." It should be noted, however, that similar predictions to those made in the text can be derived if we assume that the term *some* is interpreted to mean "a few." In this case, we would assume that a "true" response would be emitted only if "a few" (say two or three) exemplars were found to possess the relevant trait.

and *woman*) than to the average similarity of *X–Y* pairs in which none of the *X* exemplars could be classified as *Y* types (e.g., *mother* and *chair*). Extending Rips's reasoning to the co-occurrence of trait terms, Figure 1 shows three distributions of feature list similarities for the three types of co-occurrence relationships whose spacing conforms to Rips's assumption.[3] Also shown is the postulated effect on C_T of changing the quantifier from *all* to *some*.

The decision time predictions of this model are based on the proportion of trait pairs that fall between C_F and C_T and therefore require second-stage processing in any given condition. One prediction is that decision times should be longer for universal than particular assertions, since, as can be seen in Figure 1, a smaller number of trait pairs falls between C_F and C_T in the latter than in the former case. A second prediction is that "false" response times should be positively related and "true" response times should be negatively related to the similarity of trait pairs, even for those trait pairs in the same co-occurrence relationship.[4] This prediction follows from the fact that as the similarity increases, there is a higher likelihood that a "false" response and a lower likelihood that a "true" response has resulted from second-stage processing. Predictions for particular types of trait pairs (e.g., those in a specific co-occurrence relationship) are easily derived by noting the relative areas of each curve that fall between C_F and C_T in Figure 1.

The two models outlined above can be contrasted in terms of the predictions they make regarding the effects on decision time of the co-occurrence relationship between the *X* and *Y* traits and the use of the quantifiers *all* and *some*. Table 1 presents the predictions of the two models in terms of relative decision times. As can be seen, a major difference between the two models is their prediction for the partial co-occurrence trait pairs. The exemplar scanning model predicts that the times for these statements will fall midway between those for the other two types, whereas the feature comparison model predicts that these trait pairs should yield the longest decision times. Additional specific predictions can be found by further study of Table 1.

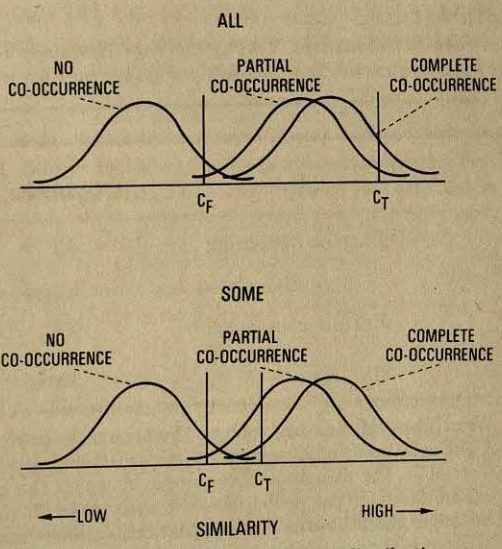

Figure 1. Spacing of similarity distributions assumed by the feature comparison model for the three types of trait pairs: pairs that are not perceived to co-occur, pairs that are perceived to co-occur in some but not all people (partial), and pairs that are perceived to co-occur in all people (complete). (Also shown is the effect on the true criterion, C_T, of changing the quantifier from *all* to *some* in the co-occurrence assertions: C_T moves down, making it easier to say "true.")

Defining Trait Sentences as Complete, Partial, or No Co-Occurrence

Unlike the noun sentences typical in cognitive research, there is no a priori method of

[3] It is important to note that many of the predictions of the feature comparison model depend directly on the assumed spacing of the similarity distributions for different types of trait pairs. Therefore, it is useful to have independent evidence about the validity of these assumptions. Without such evidence, it is possible to account for a much wider range of outcomes merely by postulating different similarity distributions.

[4] To the extent that our semantic similarity and co-occurrence estimates are highly correlated, this result could be explained by the exemplar scanning model as well. We need merely assume that the proportion of positive exemplars in a sample increases monotonically with semantic similarity. The number of exemplars that would have to be scanned before a "true" response could be emitted would then decrease as semantic similarity increased.

Table 1
Order Relationships Among Average Response Times Predicted by Exemplar Scanning and by Feature Comparison Models for Different Quantifiers and Extent of Trait Co-Occurrence

Model	Quantifier	Trait co-occurrence: Complete		Partial		None
Exemplar scanning	All	True	>	False[a]	>	False
		>				<
	Some	True	<	True[a]	<	False
Feature comparison[b]	All	True	<	False	>	False
		>		>		=
	Some	True	<	True	>	False

Note. True/false entries refer to the type of response being made in the condition.
[a] The relationship between these two outcomes depends on the proportion of X exemplars that possess the Y trait in the sample and the order in which the exemplars are examined. Assuming a random order of examination, if the proportion is greater than .5, then the false times to universal (all) assertions should be longer than the true times to particular (some) assertions. If less than .5, then the reverse should be found.
[b] The predictions of this model are based on the similarity distributions depicted in Figure 1.

deciding into which type of relationship a given trait pair, such as *witty* and *intelligent*, falls. While almost everyone would agree that the set of known robin exemplars is a subset of the set of known birds, the relationship between the set of known witty persons and the set of known intelligent persons is less clear. We can, however, determine from subjects' responses to sentences quantified by *all* and *some* what the *majority* of people believe about a given sentence. If the majority of subjects respond "true" to both the *all* and *some* versions of a sentence, then (for the majority) all of the X exemplars may be considered to possess the Y trait. When the majority of people respond "false" to the *all* version and "true" to the *some* version, then only some of the X exemplars possess the Y trait. Finally, when the majority respond "false" to both versions, the X and Y traits will not be considered to co-occur.

Similarity of Trait Feature Lists

The similarity between feature lists for the different traits was assessed by requiring that subjects rate the similarity in meaning of all relevant trait pairs. We assumed that these ratings would provide monotonic indicators of the overall similarity of each pair of feature lists (Rips, 1975; Smith et al., 1974).

Experiment 1

Experiment 1 was designed to examine the contrasting predictions of the two models. Ratings of the similarity of trait pairs and decision times to verify universal, particular, and "a person" assertions about these trait pairs were recorded.

Method

Subjects

Nine male and nine female college students each participated in three 1-hour sessions in partial fulfillment of an introductory psychology course requirement. All of the participants were native speakers of English.

Apparatus and Software

The decision time data were collected using a PDP-12 laboratory computer. Responses were made to stimuli, displayed on the video screen, on two telegraph keys, one labeled "true," the other "false." A user-oriented computer program was used to control and randomize stimulus pairs and to record the response latency and which of the two keys had been pressed. Decision times were accurate within 1 msec.

Procedure

Participants were told that the study dealt with their reactions to various personality characteristics of people and that they would have to participate in

three separate sessions, each lasting from 45 minutes to 1 hour and separated by 3 to 5 days.

Semantic similarity and co-occurrence ratings. All of the participants completed two questionnaires. One was filled out in the first session and one in the third, counterbalanced for order over participants. Both questionnaires presented all possible pairs of 12 different trait adjectives (see Figure 2). The semantic similarity questionnaire asked the participants to indicate "how similar in meaning" the two terms were on a 20-cm unmarked scale anchored by "not similar in meaning" and "identical in meaning." The other, co-occurrence, questionnaire asked the participants to indicate, "How likely is a(n) _____ person to also be _____?" Unmarked 20-cm scales were again used, but in this case they were anchored by "not likely" and "extremely likely." The participants were told to complete the semantic similarity scales on the basis of each term's "dictionary definition" but were not given a particular instruction regarding the co-occurrence ratings. Participants were run individually in an isolated cubicle and took as much time as they needed to complete each questionnaire.

Forced-choice decision task. The procedures for the three decision tasks were virtually identical. One was conducted in the first session after the first questionnaire was completed, and two were conducted in the second session. Order of task was counterbalanced across the participants. Upon arrival at the computer laboratory, participants were seated in front of the PDP-12 and video stimulus display. They were told that pairs of trait terms would appear on the video screen in blank spaces in a cardboard mask that was placed on the video screen. In a particular session, one of the three following sentences was written on the mask: "A(n) _____ person is also a(n) _____ person";[5] "Some _____ people are also _____"; and "All _____ people are also _____." The subjects were told that when a trait pair appeared on the screen, they were to indicate whether the *entire sentence* was true or false by pressing the right (left for half of the subjects) telegraph key if they thought it was true and the left (right) key if false. They were told to read the entire sentence each time that a new pair of trait terms was presented. They were also told to think about each sentence carefully before responding, but as soon as they were sure of the answer to press one of the keys. After demonstrating to the subjects how to position their hands near the telegraph keys, the experimenter began a short program that presented five practice trait pairs (not in the actual experimental list). The experimenter observed the participants while they completed these practice trials, reinstructing them if necessary. After these trials were completed, and following a 2- to 3-minute delay, the main program was initiated. The experimenter left the room, instructing the participant that the word *finished* would appear in both blank spaces on the video display when the task was completed.

The main program presented each word in the trait pair virtually simultaneously. Measurement of the response latency began the moment that the two words appeared on the screen and ended either when one of the two keys was pressed or when a 15-sec maximum had been reached. There was a 4-sec intertrial interval, during which time the display was blank, between the presentations of the stimulus pairs. No "ready" signal was used in this study. Each participant was presented with a given pair of trait terms only once. The two terms in a given pair were presented in only one order, which was held constant over participants.

Results

The data were analyzed in an attempt to examine several major issues. Of initial concern was whether the semantic similarity ratings (uncommon in implicit personality research but common in cognitive research) would yield a multidimensional representation similar to that obtained from the co-occurrence ratings (which are more common in studies of implicit personality). The second analysis studied the effect of the universal and particular quantifiers on decision times for the three types of trait pairs: complete, partial, and no co-occurrence. In the third analysis, the relationship between semantic similarity and "true" and "false" decision times was examined. The fourth analysis examined the ability of the semantic similarity ratings to explain the effects of the co-occurrence relationships on decision times.

Multidimensional Structure of Trait Terms

The structure inherent in the semantic similarity ratings was compared to that obtained with the more common co-occurrence rating method. The average (over participants) semantic similarity and the average co-occurrence rating between each pair of the 12 trait terms used in the study were computed. The two half-matrices (the trait terms were paired in only one order) were then separately analyzed using KYST2 (see Kruskal, Young, & Seery, Note 1), a monotone multidimensional scaling program. The en-

[5] For reasons of clarity, the results for this decision task will not be presented. It should be noted, however, that they were completely consistent with the results from Experiment 2.

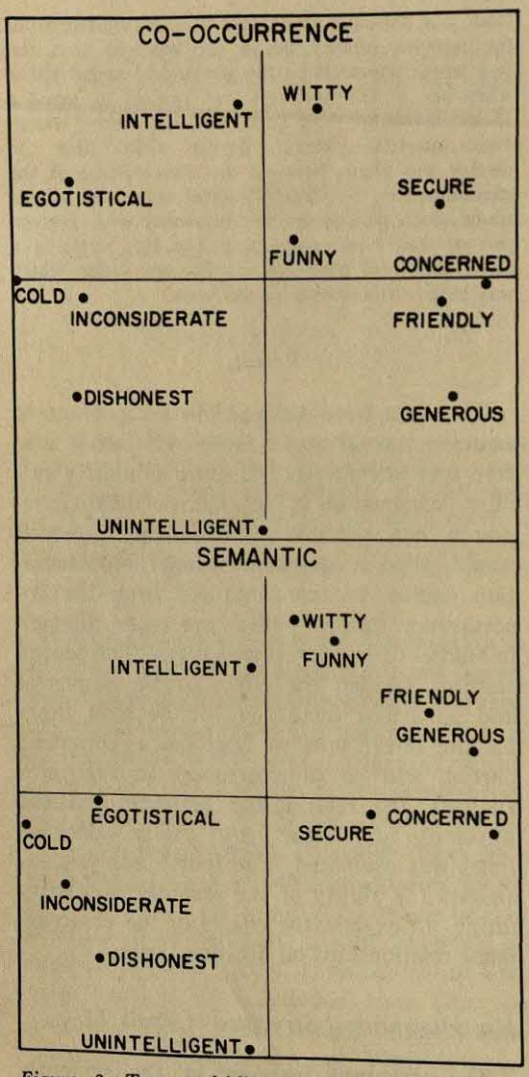

Figure 2. Two multidimensional scaling solutions for the 12 trait terms used in Experiment 1. (The top panel shows the solution for co-occurrence ratings, rotated to its principle components. The bottom panel shows the solution for semantic similarity ratings of the same traits, rotated to minimize the difference between the two solutions. The high correspondence between the two solutions is of most interest.)

tries in each lower half-matrix of the two types of ratings were analyzed as direct distance estimates. Two-dimensional solutions seemed to provide reasonable representations of both data sets. The one-dimensional stress (Formula 1) values were .2,976 for the co-occurrence ratings and .2,302 for the semantic similarity ratings. A two-dimensional fit reduced these values to .1,245 and .0,817, respectively. It seemed inappropriate to fit a three-dimensional solution to the data, given the small stimulus set.

The top panel in Figure 2 contains the two-dimensional solution for the co-occurrence ratings, rotated to its principal components. The bottom panel contains the results for the semantic similarities rotated to minimize the difference between the two solutions. The two solutions yielded remarkably similar results. As in Rosenberg and Sedlak's (1972) work, the two most important dimensions in this trait set seem to be socially good–bad and intellectually good–bad. In short, not surprisingly, the participants in our study seemed to have an implicit personality theory similar to that found for other subject samples in other laboratories. More important, however, the obvious congruence of the semantic similarity and co-occurrence structures implies that processes involved in implicit personality may be related to more basic semantic memory processes, as we have argued.

Complete, Partial, and No Co-occurrence

Of major concern in this experiment were the effects on decision time of universal and particular assertions involving trait pairs that were defined as being in a complete, partial, or no co-occurrence relationship. In order to examine the predictions outlined in Table 1, the 66 sentences quantified by *all* were divided into two groups according to the majority response (true vs. false) given to each. The same was done for the corresponding 66 sentences quantified by *some*. The mean decision time (over participants) for those participants whose response agreed with the majority was then computed for *each* universal assertion and for *each* particular assertion. The 66 trait pairs and their associated decision times were divided into three groups: those for which the majority response was "true" to both the universal and particular versions (complete co-occurrence), those for which it was "false" and "true," respectively (partial co-occurrence), and those for which it was "false" for both versions (no co-occurrence). There were no trait pairs in which the

Table 2
Mean Decision Time (in sec) to Respond to the Complete, Partial, and No Co-Occurrence Trait Pairs When Quantified by All *and* Some

	Trait co-occurrence					
	Complete (n = 16)		Partial (n = 33)		No (n = 17)	
Quantifier	Time	Response	Time	Response	Time	Response
All	3.719	True	3.540	False	3.134	False
Some	3.314	True	3.811	True	3.730	False

Note. n = the number of trait pairs in each co-occurrence category.

majority response was "true" for the universal, but "false" for the particular, version.

Table 2 presents the mean (over trait pairs) decision times for the *all* and *some* quantifiers applied to the three types of trait pairs. A 2 (quantifier) × 3 (type of trait pair) analysis of variance was performed.[6] Contrary to the feature comparison model, the main effect of the type of trait pair was not significant, $F(2, 63) = 1.14$. Also contrary to the feature comparison model, the time to verify sentences quantified by *some* was significantly longer (rather than shorter) than the time to verify those quantified by *all*, $F(1, 126) = 5.57$, $p < .05$. The interaction between quantifier and trait pair type was highly significant, however, $F(2, 126) = 18.33$, $p < .001$. For universal assertions, subjects negated the no co-occurrence pairs much faster than they affirmed the complete co-occurrence pairs. In contrast, for the particular assertions, subjects negated the no and partial co-occurrence trait pairs much more slowly than they affirmed the complete co-occurrence pairs. This pattern of mean reaction times seems to conform more closely to that predicted by the exemplar scanning model than to that predicted by the feature comparison model (compare Tables 1 and 2).

Decision Times and Semantic Similarity

Recall that the feature comparison model argues that "true" response times should decrease and "false" response times should increase as the semantic similarity of the X and Y trait terms increases. To examine these predictions, the decision times were divided according to the participant's "true" and "false" responses, and by quantifier. Each set was then correlated with its associated semantic similarity ratings, separately for each participant. This analysis yielded one "true" correlation and one "false" correlation per quantifier for each participant. Fisher's z transformations of these correlations served as the raw data for the analyses below.

Table 3 presents the mean "true" and "false" correlations for the two quantifiers. Only the mean "true" correlations were significantly different from zero for the sentences quantified with *some*, $t(17) = 4.62$, $p < .01$, whereas only the mean "false" correlations were significant for the sentences quantified with *all*, $t(17) = 2.80$, $p < .05$. The correlations between rated similarity and decision time were examined for each subject. These were significant ($p < .05$) and in the predicted direction for two "true" and six "false" cases when *all* was used, and for eight "true" and three "false" cases when *some* was used. Thus, the average t test results seem to

[6] Actually, two different analyses of variance were computed. In one, the fact that there were more intersection pairs than the other types was treated as representative of the entire population of trait terms, and a least squares solution was therefore employed. In the second analysis, the unequal ns were assumed to be artifactual, and an unweighted-means analysis was used. Since the conclusions were identical, only the results of the second analysis are presented in the text. In addition, it should be noted that the error terms in both of these analyses were based on variability over sentences rather than subjects. The logic of using sentences to generate the error term has been outlined by Clark (1973).

Table 3
Mean of Fisher z Transformed Correlations Between Decision Times and Semantic Similarity Ratings for "True" and "False" Responses to Sentences Quantified With All *and* Some

Response	Quantifier	
	All	Some
True	−.06	−.26**
False	.15*	.08

* $p < .05$ (two-tailed). ** $p < .01$.

represent the proportion of subjects for whom the semantic similarity – decision time correlation was as predicted.

A 2 (true/false) × 2 (quantifier) mixed analysis of variance on these transformed correlations indicated that the "true" response correlations were significantly different from the "false" response correlations, $F(1, 17) = 9.82$, $p < .01$. The effect for type of statement was not significant, $F(1, 17) = 1.48$, $p > .05$, and the interaction between true/false and quantifier was also not significant, $F(1, 17) = 2.85$, $p > .10$. Separate t tests on the difference between the mean "true" and "false" correlations for each quantifier supported this interaction result; the difference was significant in both cases ($p < .05$). The finding that "false" response times were more positively related to semantic similarity than "true" response times across both quantifiers offers relatively strong support for the feature comparison model.

It appears that the results of the co-occurrence analysis (Table 2) supported the exemplar scanning model, whereas the results from the semantic similarities (Table 3) supported the feature comparison model. One plausible explanation for this outcome is that one or more of our assumptions about the nature of the models may require modification. In particular, recall that the predictions of the feature comparison model described in Table 1 were based on an extension of a suggestion made by Rips (1975), namely, that the distributions of semantic similarities for complete, partial, and no co-occurrence trait pairs would be spaced as depicted in Figure 1. To examine the validity of this assumption, we computed the mean similarity rating for each trait pair (only for those participants whose "true"/"false" response agreed with the majority). The average (over sentences) similarities for the three types of sentences were then derived, and they are presented in Table 4. An unweighted-means 2 (quantifier) × 3 (type of trait pair) analysis of variance of these data indicated that there was a highly significant difference among the three types of trait pairs, $F(2, 63) = 350.66$, $p < .001$. The trait pairs defined as being in a complete co-occurrence relationship were indeed seen as much more similar than the no co-occurrence pairs. Partial co-occurrence trait pairs were midway between these two, but, contrary to expectation, they were closer to the no co-occurrence than to the complete co-occurrence trait pairs. No other effects were found to be significant.

As we will discuss below, these similarity results suggest an explanation for the pattern in the previously presented mean decision times that is based on a revised feature comparison model. With this explanation in mind, we examined the ability of the semantic similarity estimates to predict variations in response times *within* each of the three types of trait pairs. The feature comparison model makes the strong prediction that "true" response times should be positively related and "false" times negatively related to similarity, even within these trait pair types. Table 5 presents the correlation (over sentences) between the mean similarities for each trait pair type. As can be seen, the correlations were significantly different from zero in two of the six cases: the true times to the complete and partial co-occurrence pairs that were quanti-

Table 4
Mean Semantic Similarity of Complete, Partial, and No Co-Occurrence Trait Pairs Quantified by All *and* Some

Quantifier	Trait co-occurrence		
	Complete	Partial	No
All	14.19	6.36	3.48
Some	13.52	8.77	2.62

Note. Similarity was rated on a 20-point scale. Higher numbers indicate greater similarity.

fied by *some*. The sign of each of the correlations was in the direction predicted by the feature comparison model, however.

Discussion

Taken together, the results from this experiment offered some support for both models proposed in the introduction.

Mean Decision Times

With one exception, the pattern of mean decision times for the three types of trait pairs seemed to support the exemplar scanning model fairly well. It took less time for subjects to affirm that some X were Y when all of the X exemplars possessed the Y trait than when only some did. Similarly, it took less time to say that all Xs were not Ys when none of the X exemplars possessed the Y trait than when some of the X exemplars did. On the other hand, the time to verify that some Xs were Ys when only some X exemplars possessed the Y trait was not midway between the complete and no co-occurrence trait pairs, as predicted (Tables 1 and 2); instead, it was the longest time.[7]

Decision Time and Semantic Similarity

Although the mean decision times seemed to support the exemplar scanning model, some aspects of the correlations between semantic similarity and decision time supported predictions of the feature comparison model. As predicted, semantic similarity ratings correlated more positively with "true" decision times than with "false" decision times (Table 3). However, the fact that the correlations for "false" responses to particular assertions and "true" responses to universal assertions were not significantly different from zero is somewhat inconsistent with the feature comparison model. The correlations within each type of trait pair also provided only weak support for this model.

The Feature Comparison Model Revisited

It is possible to offer a consistent explanation for the entire pattern of results by revising our assumptions about the effects of quantifiers on the cut points, C_F and C_T, in the feature comparison model and by considering some of the methodological inadequacies of this experiment. Take the latter point first. In this study, each participant produced only one decision time and one semantic similarity rating per trait pair. If the error variability in the decision times were reasonably large, it could account for the failure to find consistently significant correlations for individuals between semantic similarity ratings and decision times (Table 3). Furthermore, the fact that the standard deviation of the mean semantic similarity ratings (over trait pairs within a given type) was very small (min. $\hat{\sigma} = .826$, max. $\hat{\sigma} = 1.974$, on a 20-point scale) could explain the failure to find significant correlations within each type of trait pair (Table 5).

Table 5
Correlation Between Mean Decision Times and Mean Semantic Similarity Ratings for Each Type of Trait Pair and for Each Quantifier

Quantifier	Trait co-occurrence: Complete ($n = 16$)	Partial ($n = 33$)	No ($n = 17$)
All	−.24	.04	.01
Some	−.67*	−.41*	.06

Note. n = the number of trait pairs used to compute each correlation.
* $p < .05$.

Our original predictions for the feature comparison model were based on Rips's (1975) assumption that the semantic similarity distribution for the partial co-occurrence trait pairs would be more similar to

[7] It should be noted that the average semantic similarity results can be used to explain this outcome. If a large majority of the X exemplars did not possess the Y trait in the partial co-occurrence trait pairs, then the participants would be expected to take a long time to determine that at least one exemplar possessed the Y trait. On the average, most of the exemplars in the sample would have to be examined before an answer was given. Thus, the decision time should be almost as long as the time to assert that not even one exemplar possessed the relevant trait.

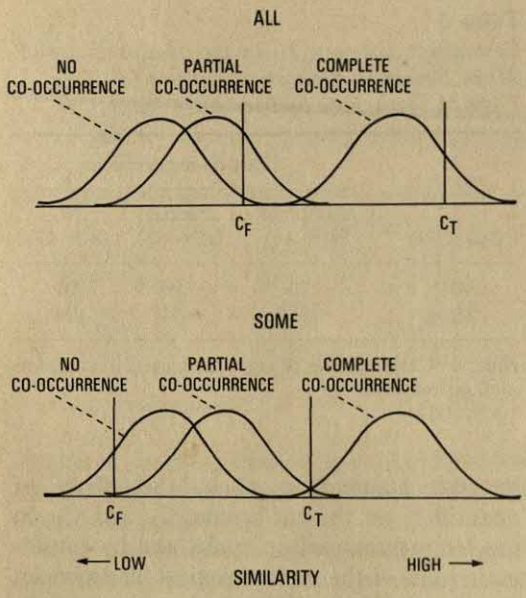

Figure 3. Spacing of similarity distributions obtained for the three types of trait pairs (no, partial, and complete co-occurrence) in Experiment 1. (Also shown is the effect on the "true," C_T, *and* the "false," C_F, criteria of changing the quantifier from *all* to *some*, as assumed by the revised feature comparison model.)

the complete than to the no co-occurrence similarity distributions (see Figure 1) and that changing the quantifiers would only affect the position of C_T. The mean semantic similarity results (Table 4) suggest that for our trait terms, the first of these assumptions was not satisfied. The average similarity of the *X–Y* terms in the partial co-occurrence pairs was closer to that for the no co-occurrence than the complete co-occurrence pairs. With this finding in mind, it is possible to explain the *exact* pattern of means obtained for the two types of sentences (Table 2) by assuming that the change in quantifier affected the placement of *both* C_F and C_T. That is, changing from universal to particular assertions may lower both C_F and C_T rather than just C_T. The effect of such a change in assumptions can be seen in Figure 3. Three distributions of semantic similarities, one for each type of trait pair, are presented so that the differences in their means correspond, roughly, to the differences in semantic similarity ratings reported in Table 5.

The predictions for this new version of the feature comparison model can be derived by noting the area of each distribution that falls between the cut points. The area is a direct index of the proportion of trait pairs (within the trait-pair type) that requires extra processing time. Note that in the *all* case, most of the complete co-occurrence pairs are between the two cut points, thereby producing long, "true" decision times. A moderate number of the partial co-occurrence pairs falls between the cut points, resulting in moderate times for "false" responses to these pairs. Since most of the no co-occurrence pairs are below C_F, very fast "false" responses would be expected. On the other hand, in the *some* case, most of the complete co-occurrence pairs are above the new C_T cut point, and fast "true" responses would be expected. Almost all of the partial co-occurrence pairs are between C_F and C_T, resulting in very long (rather than moderate, as predicted earlier), "true" responses. Finally, the large proportion of no co-occurrence pairs falling within C_F and C_T should produce longer "false" response times for these pairs. As can be seen, this describes the exact pattern of decision time means that was obtained (Table 2).[8]
